The first process in these analyses is usually to evaporate

a portion of the water to dryness, with the view of ascertaining the total amount of solid matter.

The object of this is merely to give a check upon the total of separate constituents. Afterwards each constituent is estimated by itself, a fresh portion of water being used, if possible, for each. In the present case, as soon as the evaporation had proceeded so far as to cause the commencement of crystallisation, pungent fumes of hydrochloric acid began to be given off in abundance. This was evidently owing to the presence of chloride of magnesium, which, like chloride of aluminium, is decomposed on evaporating its solution into the base and hydrochloric acid. As, from the small quantity of water sent me, I was obliged to employ the dry saline mass for the purpose of estimating some of the constituents, I did not dry the mass completely enough (that is, at a high temperature) to make its weight an efficient control on the subsequent analysis, which, if I could have foreseen what afterwards occurred, I should certainly have done.

On summing up the amounts of acids and bases obtained,—hydrochloric and sulphuric acids, soda, lime, and magnesia,—I was surprised to find that in four out of the five cases the acids were quite insufficient to neutralise the bases; in the fifth case the difference was unimportant. I naturally suspected some error in my analysis, and repeated a few of the processes with such small quantities of water as I could spare, without finding any errors of importance. I was driven, therefore, to seek for some other acid which must have escaped detection. Phosphoric acid was sought for in vain; but on applying the tests for nitric acid, it at once appeared that, in the very four cases mentioned, it was present in abundance, while in the fifth mere traces of it were found.

There are some substances which, from peculiar circumstances, it is difficult to estimate quantitatively in a direct manner, and it has, therefore, been usual in compounds containing them to weigh all the other ingredients, and then set down the difference which remains unaccounted for as their weight. Boracic and nitric acids are of this class. The only method recommended for directly estimating the nitric acid of mineral waters was to precipitate the chlorine, iodine, and bromine by sulphate of silver, and then to distil the concentrated liquid with an excess of sulphuric acid. Nitric acid with a little sulphuric acid comes over into the receiver in which a solution of baryta is placed, with which the acids combine. By then slowly evaporating the solution to dryness in the air, the free baryta is converted into carbonate; water leaves the carbonate, and sulphuric acid dissolves the nitrate, in which the baryta being estimated by sulphuric acid in the usual way, the quantity of nitric acid equivalent to it is found. This is a very round-about process, and the distillation especially is most objectionable. The retort is pretty sure to break, unless a sand-bath is used, which retards the operation, and it is quite impossible to bring over the whole of the acid, which remains hanging about the body and neck of the retort. However, with the very small quantity of water that remained, I tried the process, and in one case succeeded in obtaining five-eighths of the whole quantity of nitric acid to be accounted for; in the other cases the loss was much greater. I was obliged, therefore, to rest contented with estimating the nitric acid by difference.¹

¹ Far superior modes of estimating nitric acid have been introduced within the last ten or twelve years, but I was not then acquainted with them.

The waters from Aden were named as follows:—1, Bantan well; 2, Parsee well; 3, Turkish well; 4, Jaffron well; and 5, Lower Tawella. Their composition is given in the accompanying tables; the specific gravities were taken at the temperature of the atmosphere, and reduced by calculation to 60°, the expansion being assumed to be the same as that of pure water. The quantity to which the contents are referred is the imperial pint of 8750 grain measures, or one-eighth of an imperial gallon.

Names of Wells.	Banian.	Parsee.	Turkish Well.	Jaffron.	Lower Tawella.

I was until lately under the impression that this was the first time the water of the Aden wells had been analysed. I find, however, that some years previously Dr. Giraud had cursorily examined seven specimens of such waters, at the instance of the Medical Board, with the following result, which he has kindly allowed me to communicate. I have added the third and fifth columns for the sake of comparison with my analyses:—

Name.	Specific gravity of distilled water = 1000.		Saline contents.	
	At 80° F.	At 60° F.	In 1000 grains.	In an Imperial pint.
1. Bantan Well ..	999	1002	1.16	5.08
2. Bir ud Dowla ..	999	1002	1.50	6.08
3. Bir Zawool ..	1000	1003	2.75	12.07
4. Gaol Well ..	1001	1004	5.58	24.50
5. Bir Senar ..	1001	1004	8.41	36.94
6. Bir Zaffran ..	1002	1005	10.04	44.15
7. Un-named ..	1000	1003	8.70	38.18
8. Ras Ma' (contained bromine) ..	..	..	59.00	258.12

No quantitative analysis was then made, but Dr. Giraud remarks that No. 7 contained a large quantity of salts of lime.

Amongst these waters, there are only two which bear the same name as those in my list, the Banian well and the Zaffran well. Whether the Zawool is the same as

² From a well experimentally sunk on the Isthmus, very near the sea, at the south-eastern extremity of the inner line of fortification, at the foot of the rocks, the water was at first sweet, but after a time the sea appeared to penetrate into it, and it became useless. (See Lieut. Wilkins' Report.)

the Lower Tawella of my list is doubtful. But the difference in character of those two, as they appear in the two lists, is so great as not to be easily reconciled; either there must be some confusion of names, or the water of the wells is liable to very great variation in quality. Perhaps some of the officers at Aden may be able to clear up this point. A list of the various wells in Aden, with an exact description of their localities, and other particulars, is much wanted.

The discovery of so large a quantity of nitric acid in well water was at the time, I believe, unparalleled; but a few years after other cases of a similar nature were found to occur, and on this side of India. In 1854 some water was sent for analysis from Nassick, drawn from a certain well in the gaol, which water was so impregnated with salts as to be unfit for any purpose but that of washing. Dr. Giraud found it to contain so much nitric acid that "on evaporating the water to dryness, and igniting the residue, copious red fumes of nitrous and hypo-nitrous acids were disengaged from the decomposition of the nitric acid of the nitrates, by the organic matter previously held in solution in the water." Again, in the following year, four samples of water, from different wells in the town of Nassick, being sent for analysis, three of them proved to be ordinary spring water, of tolerable purity; but the fourth, from the "Bhunder Kallee" well, was found to be even more strongly impregnated with nitrates than that from the gaol. In this case, also, copious red fumes were given off in heating the saline residue. The proportion of silica, too, appears most unusually large; perhaps the sulphate of lime was not thoroughly extracted from it. The composition of these waters is given below. I have added a column with a view to facilitate comparison with my analysis of the waters from Aden. The nitric acid is estimated by difference. The water from the Nassick wells is said to vary very much according to the season of the year. These waters were drawn in October and November.

Specific gravity .. {	Gaol Well.		Bhunder Kallee Well.

(To be continued.)

On Perchloric Acid and its Hydrates,¹
by Professor Roscoe.

ALL the knowledge we possess of the quantitative relations of perchloric acid is the determination of the composition of the potassium salt, first analysed by Stadion, in 1816, and afterwards by many other chemists. The perchloric anhydride has not been isolated, and no analysis of the aqueous acid has ever been made. We can only account for the neglect with which chemists have treated the highest and yet the most stable of the oxides of chlorine, by the fact that the preparation of the acid in large quantities has been attended with great difficulties. The best method for preparing aqueous perchloric acid is to decompose chlorate of potassium with hydrofluosilicic acid, to boil the chloric acid thus obtained down, which splits up into lower oxides of chlorine, which escape in the gaseous state, impure perchloric acid being left behind, which is purified by distillation. The acid thus obtained is in appearance not to be distinguished from oil of vitriol, being a colourless, heavy, thick, oily, corrosive liquid, giving off by heating dense white fumes. By heating the aqueous perchloric acid with four times its volume of concentrated sulphuric acid, the latter takes water from the first, dense white fumes are evolved, a yellow mobile liquid distils over, afterwards thick oily drops appear, which, when coming in contact with the yellow liquid, form white crystals, previously obtained by Serullas, but in such small quantities that he was unable to analyse that substance, which, prepared in this way, contains always sulphuric acid, and is therefore not fit for analysis, and requires redistillation. Heated, however, to 110° C., the crystals decompose, and split up again in the yellow liquid, which distils over at a low temperature, and the thick oily liquid remains in the retort. The yellow liquid thus obtained is pure perchloric acid, a body not known before, and can be obtained also by distilling one atom of perchlorate of potassium with four atoms of sulphuric acid. In the pure state it is perfectly colourless, but commonly slightly yellow, owing to the presence of lower oxides of chlorine. Perchloric acid is one of the most powerful oxidising agents known; a single drop brought into contact with charcoal, paper, wood, alcohol, &c., immediately causes explosive combustion, falling not short in violence of that of chloride of nitrogen, and brought on the skin fearful wounds are produced, which do not heal for months. Like nitric acid, it cannot be distilled without decomposition, but it darkens, and heated stronger, decomposes with explosion. It cannot be kept for any length of time; even sealed up in glass bulbs, which are placed in the dark, it decomposes suddenly after some time, smashing the vessel containing it. It mixes with water with a hissing noise and evolution of heat, uniting and forming the same crystals which were mentioned before, and were used for preparing the pure acid. These crystals are the monohydrated perchloric acid. They melt at 50° C., and heated to 110° C., split up in pure perchloric acid, which distils over, and an oily liquid boiling at 200°, which is also obtained by boiling aqueous perchloric acid till dense white fumes are given off. That oily acid has a constant composition containing 72.3 per cent. pure perchloric acid and 27.7 per cent. of water. This per-centage corresponds, however, to no definite hydrate of simple atomic composition, but follows the same general relations respecting composition and boiling point, which,

¹ Might not the red fumes rather be partly owing to the reaction of the hydrochloric acid disengaged from the hydrated chloride of magnesium, on the nitrates producing chlorine and chloro-nitric gases?

¹ Read before the British Association.

as I have shown previously, hold good for so many aqueous acids, namely, that the phenomena of constant boiling point and constant composition depend chiefly upon physical, and not on chemical attractions.

TECHNICAL CHEMISTRY.

On the Chemical Manufactures of South Lancashire, by Drs. SCHUNCK, ROSCOE, and SMITH.

Sulphuric Acid.—This is an important manufacture, and quite indispensable in the production of many other articles, as well as in the manufacturing processes. To produce it economically on a large scale was of considerable importance, and a great degree of economy was practised. Few manufacturers employed sulphur, most of them using pyrites. In burning the pyrites from eight to ten of sulphur remained behind and was lost. Mr. Spence, of Manchester, had, however, reduced this loss to two. The introduction of Spanish and Portuguese pyrites had caused the rise of a new branch of industry in the extraction of a small quantity of copper which these ores contain. In Hill's process of purifying gas, hydrated peroxide of iron was used instead of lime. When the material could be no longer used for purification, it was found to contain sulphur, and Mr. Spence used this sulphur for the production of sulphuric acid. From one ton of the material he obtained about one and a-quarter ton of hydrated sulphuric acid. Mr. Harrison Blair's improved sulphur-burner was especially valuable, as economising space in the chambers, by preventing the sulphurous acid from being diluted with too large an excess of air, as is the case in the ordinary burners. The tendency in this district has been to increase the size of the sulphuric acid chambers, the largest being 112,000 cubic feet. Many manufacturers employ Gay-Lussac's method, invented sixteen or seventeen years ago, for economising nitric acid. By this means a saving of more than 50 per cent. of nitrate of soda is effected; but others do not employ this method, as with the low price of nitrate of soda, at 12l. per ton, it does not pay to collect and absorb the waste oxides of nitrogen. The use of platina stills for the rectification of sulphuric acid has now been almost entirely abandoned, and their place supplied by glass retorts, which are made larger and of better quality than formerly. The weekly production of sulphuric acid of specific gravity 1.85, exclusive of what is used in the manufacture of soda ash, is 700 tons.

Soda.—This is a most important manufacture. Few changes in the principle of manufacture have taken place during the last ten years, the essential points of the original method of Leblanc (1798) being still adhered to. The extent of the manufacture has largely increased since the year 1851. The value of alkali made annually in England is 2,000,000l.; of this half is made in South Lancashire and half in the Newcastle district. The following statistics apply to the South Lancashire alkali trade, per week, in 1861:—Common salt decomposed per week, 2600 tons; sulphuric acid used, 3110 tons; hydrochloric acid produced, 3400 tons; soda ash sold per week, 1800 tons; salt cake sold per week, 180 tons; soda crystals ditto, 170 tons; bicarbonate soda ditto, 225 tons; and caustic soda ditto, 90 tons. Since 1852 the alkali trade of South Lancashire had more than tripled. The large quantity now produced was manufactured in about twenty-five works, chiefly situated at St. Helen's, Runcorn Gap, Widnes Dock, near Warrington, the

neighbourhood of Bolton, and Newton Heath. None of the patents for improving the manufacture of alkali had changed the process materially. The improvements of detail since 1851 have been the following:—1. Greater attention to economical working in all the branches. 2. The process of lixiviation of black ash is more completely accomplished than formerly by the arrangement of Mr. Shanks. 3. In some works the black ash is now made by machinery. 4. The soda is now in many alkali works packed in casks by machinery. Since 1851, a new branch of the manufacture has been introduced by the preparation of solid caustic soda, which is largely exported to America and other places. The proposition recently made by Kuhlmann for the employment of the alkali waste as a cement is a very old idea, Mr. Deacon, of Widnes, having used it for making floors for twelve years. In conclusion, the report recognised the important additions to our knowledge of the theory of soda manufacture made by Mr. Gossage.

Bleaching Powder.—155 tons of this powder is made in this district. The only remarkable points in the manufacture is an ingenious process of preparing chlorine without the use of biniodide of manganese, patented in 1858 by Mr. Shanks, of St. Helen's, and the regeneration of peroxide of manganese from the waste liquors containing chloride of manganese.

Chlorate of Potash.—From four to five tons of this salt are made weekly in this district, and it is used for match making.

Hypo-sulphite of Soda.—Three tons weekly are made, and are used by paper makers, photographers, and by bleachers as an antichlor.

Silicate of Soda.—This compound is used as a substitute for cow-dung in calico printing, and by soap manufacturers in place of the resins formerly in use. About ten tons weekly are produced in this neighbourhood.

Arseniate of Soda.—This salt is used as a substitute for cow-dung in calico printing, for which purpose it is better adapted than the silicate of soda, as it does not so much attach the alumina mordants. Ten or twelve tons are produced weekly in this neighbourhood.

Bichromate of Potash.—There is nothing new in the manufacture of this salt. About fourteen tons are produced weekly in the district.

Prussiate of Potash.—From four to five tons of yellow prussiate of potash and one ton of red prussiate are produced in this district weekly.

Superphosphate of Lime.—The weekly production in this district is 5600 tons.

Alum.—Before 1845 the alum manufactured in this district was confined to a small quantity from pipeclay, our chief supplies being derived from Whitby. By the old process 60 tons of the oolitic shale of Yorkshire was required to produce one ton of potash alum and one ton of Epsom salts. By Mr. Spence's process 50 tons of shale yield 65 tons of ammonia alum. Mr. Spence employs the shale found underlying the seams of coal in this district. In 1850-51, Mr. Spence made about 20 tons per week. The quantity now made by him amounts to 110 tons. Fully half of the total quantity manufactured in England (300 tons per week) is made by this process.

Protosulphate of Iron.—This salt is manufactured in large quantities in this district, principally for the use of dyers, the amount being about eighty tons per week.

Pyroligneous Acid.—The only improvement introduced into the manufacture of this acid during the last

few years consists in the use of sawdust instead of wood in the process of destructive distillation. The quantity of acid manufactured weekly in Manchester is 12,000 gallons, containing about 4 per cent. of glacial acid. The value of the acid is 3*l.* per ton, whilst that of the tar is 4*l.* to 4*l.* 10*s.*

Compounds of Tin—Chlorides of Tin.—The quantity of these compounds (estimated as crystallised protochloride of tin) manufactured in this district amounts to about sixteen and a-half tons per week.

Stannate of Soda.—This compound has for some time been extensively used for the purpose of preparing calicoes which are intended to be printed with so-called steam colours.

Sulphate of Baryta.—Of this salt, which is usually sold under the name of *Blanc fixe*, about two tons are made in this district by precipitation.

Nitric Acid.—About forty-eight tons of nitrate of soda per week are used in this district for making nitric acid. The salt yields its own weight of acid. Nitric acid is used here for making the nitrates of copper, lead, alumina, and iron, for oxidising tin, for etching, and, latterly, for making aniline.

Oxalic Acid.—One of the most important and interesting of the new manufacturing processes is one for the preparation of oxalic acid, invented and patented by Messrs. Roberts, Dale, and Co., gentlemen to whom we owe a number of highly ingenious and useful practical processes. The quantity of acid manufactured by Messrs. Roberts and Dale amounts to nine tons per week, with capabilities of extension to upwards of fifteen tons. To give an idea of the effect which the introduction of this process has had on the market, it may be mentioned that the selling price at this time is 8*d.* to 9*d.* per lb., whereas in 1851 it was 15*d.* to 16*d.* per lb. Oxalic acid is used extensively in calico printing, woollen dyeing, woollen printing, silk dyeing with wood colours, in straw bleaching, and for making binoxalate of potash, so-called "salt of lemons."

Starch and Artificial Gums.—About twenty tons of starch and thirty-four tons of gum substitutes, made by roasting farina and other kinds of starch, are produced in this district per week.

Purification of Resin.—Several very interesting and successful processes have lately been patented by Messrs. Hunt and Poehin, of Salford, for the purification of resin. The aim of these gentlemen, who have devoted a large amount of time and attention to this subject, is to produce a bright, nearly colourless, solid, and brittle resin, from the common, dark, and impure commercial article. About sixty tons per week of this clarified resin is now manufactured in this district under this patent.

Organic Colouring Matters.—There are few substances of more importance to the manufacturers of this district than those which are employed in imparting colours to the various fabrics, especially those of cotton, produced here. Of these substances, the majority are derived from the animal or vegetable kingdom. Indeed, with the exception of oxide of iron and chromate of lead, very few mineral substances are at the present time made use of alone by the dyer or printer. The great intensity, beauty, and variety of the dyes which are wholly or in part composed of organic matter, causes them to be preferred, and the increase of skill and knowledge of scientific principles on the part of dyers and printers have also led to their more exclusive employment, when it is stated that the quantity of dye-

woods (logwood, peachwood, saffronwood, barwood, fustic, quercitron bark) consumed weekly by the dyers of this district amounts to 300 or 400 tons; that the weekly consumption of the same by printers is about 60 tons; that from 150 to 200 tons are in the same time converted into extracts; that 150 tons per week of madder are used up, exclusive of what is used for garancine, &c., some idea of the magnitude of the interests depending on the employment of the materials may be formed. With the exception of a new method of reducing indigo by means of finely-divided metals, patented by Leonard, we do not suppose that any important improvement has been introduced in connection with this dye-stuff. Of less importance in the art of dyeing is madder, the material with which the most permanent reds, purples, and blacks are produced. The methods which have been proposed for more effectually utilising this important dye-stuff are very numerous indeed, though exceedingly few of them have been found to be of practical value. They may be divided into two classes,—viz., those having for their object to render available the greatest amount of colouring matter, and those which tend to produce more permanent or more beautiful colours. The first object seems to be perfectly attained by converting the madder by the action of acid into garancine. This preparation is becoming more and more extensively used.

Aniline Colours.—The artificial colouring matters from aniline and other bases have of late attracted much attention, and various plans have been devised for producing them. The usual method of obtaining aniline purple, the so-called "mauve," consists in submitting salts of aniline in watery solution to the action of oxidising agents, such as chromates, permanganates, or the peroxides of manganese and lead.

Disinfectants.—The manufacture of disinfectants has become a regular and constant one, and since the inquiries instituted on the subject by Mr. M'Dougall, of this city, the use of those made in this district has been enormously increased. Mr. M'Dougall manufactures, near Oldham, a disinfecting powder, in which the properties of carbolic and sulphuric acid are taken advantage of. This is used to prevent decomposition in stables, cow-houses, and among accumulations of putrescible matter, and generally for the prevention of decomposition in manures. A liquid is also prepared with carbolic acid and lime-water, which is applied for the purpose of preventing decomposition in sewers, according to the idea entertained by one of us, of purifying whole cities by preventing the generation of gases in sewer water or among accumulations of animal refuse. The liquid is also used to prevent the decomposition of animal matter when it cannot at once be made use of, especially in the case of meat brought to market, or animals that have died in the field. The solution of the powder has also been used, to some extent, in dissecting-rooms, where it immediately destroys any noxious smell, and at once liberates the fingers of the operator from the peculiarly nauseous odour which so often attaches to them. It has also been found useful in the treatment of sores, as well as of dysentery. Mr. M'Dougall has also applied carbolic acid to the destruction of parasitic insects on sheep, and has in many districts entirely driven out the arsenical preparations by the use of this acid united with fatty substances. Sheep dipped in it are not liable to be attacked by tick, even when left for some months among other sheep infected with it. Foot-rot, and other diseases of sheep, are also said to be prevented and cured by its use.

PHARMACY, TOXICOLOGY, &c.

On Phosphate of Sesquioxide of Iron,
by EMILE HEYDENREICH.

FOR several years various compounds of phosphorus, oxygen and iron, either by themselves dissolved in acids, or combined with some alkaline salts have been used to a considerable extent. Among these, the compound syrup of the phosphates of iron, soda and lime, (the chemical food,) the so-called syrup of superphosphate of iron, and the glycerol and syrup of hypophosphites of iron have been most generally used. The pyrophosphate of the sesquioxide of iron has also been brought forward by some French chemists, but did not come into use till it was offered by the late M. E. Robiquet, of Paris, in combination with the citrate of ammonia, with which it forms a soluble salt. The extended use which this latter salt has obtained, and the little notice which had been taken of the other compound of phosphoric acid and sesquioxide of iron, led me to make some experiments in this direction. The varied basic character of the phosphate of soda, from which corresponding metallic salts may be usually obtained, would naturally lead one to suppose that similar compounds of the sesquioxide of iron might be obtained by adding to a solution of them solutions of a sesquisalt of iron. This has been verified in the case of the pyrophosphate of iron $2\text{Fe}_2\text{O}_3 \cdot 3\text{PO}_5$: the reaction being $3(2\text{NaO} \cdot \text{PO}_5) + 2(\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3) = 2(\text{Fe}_2\text{O}_3) \cdot 3\text{PO}_5 + 6(\text{NaOSO}_3)$. According to this, by using the tribasic phosphate of soda, instead of the pyrophosphate, we might expect the reaction to be $3(2\text{NaO} \cdot \text{HO} \cdot \text{PO}_5) + 2(\text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3) = (2\text{Fe}_2\text{O}_3 \cdot 3\text{HO} \cdot 3\text{PO}_5) + 6(\text{NaO} \cdot \text{SO}_3)$.

On carefully adding to a solution of tribasic phosphate of soda a solution of tersulphate of sesquioxide of iron to saturation, a bulky white precipitate was obtained; the supernatant liquid was found to be decidedly acid to litmus paper. The precipitate was washed by decantation several times, thrown on a filter, allowed to drain, and finally pressed between bibulous paper. It was afterwards dried on a sand bath till anhydrous, when it was analysed to ascertain its composition; during the washing and drying, the precipitate assumed gradually a yellow tint.

One hundred grains were fused with some carbonate of soda, the mass left after ignition was removed from the crucible, introduced into a dish with some water, and every portion of oxide of iron carefully washed from the crucible; this mixture was allowed to boil, and sufficient acetic acid added to neutralise the excess of carbonate of soda. By this means, all the sesquioxide of iron was precipitated, while the clear liquid contained the phosphate of soda with some acetate of soda. The sesquioxide of iron was collected on a filter, washed and ignited; to the solution of phosphate and acetate of soda a solution of chloride of ammonium, of sulphate of magnesia and of ammonia was added; by this means the double phosphate of magnesia and ammonia was precipitated, which by ignition furnished the pyrophosphate of magnesia, from which the phosphoric acid was calculated. The result of two analyses carefully performed was:—

First Experiment.	Second Experiment.
Fe_2O_3 52.50	Fe_2O_3 52.00
$2\text{MgO} \cdot \text{PO}_5$ 73.00	$2\text{MgO} \cdot \text{PO}_5$ 74.00

112 parts $2\text{MgO} \cdot \text{PO}_5$ being equal to 72 parts of PO_5 , the following is the result:—

First Experiment.	Second Experiment.
Fe_2O_3 52.50	Fe_2O_3 52.00
PO_5 46.92 } 99.42	PO_5 47.57 } 99.57

These results correspond in composition with the phosphate of sesquioxide of iron $\text{Fe}_2\text{O}_3 \cdot \text{PO}_5$, mentioned by Will in his "Outlines of Chemical Analysis," and by Dr. Graham, in his "Elements of Chemistry." Thereaction, therefore, must be between one equivalent of phosphate of soda, and one of tersulphate of sesquioxide of iron, by which are formed: one eq. phosphate of sesquioxide of iron, two eq. of sulphate of soda, and one of sulphuric acid, which remains in the water: $2\text{NaO} \cdot \text{HO} \cdot \text{PO}_5 + \text{Fe}_2\text{O}_3 \cdot 3\text{SO}_3 = \text{Fe}_2\text{O}_3 \cdot \text{PO}_5 + 2(\text{NaO} \cdot \text{SO}_3) + \text{SO}_3 \cdot \text{HO}$.

Some further experiments were now tried to ascertain its solubility in some solvent, which might render it useful in medicine.

In hydrochloric and nitric acids, it is readily soluble; in phosphoric acid it is insoluble; in citric and tartaric acids it is slightly soluble, more so on the application of heat, forming green solutions. In phosphate of soda it is insoluble, even when heated; in tartrate of ammonia it is slightly soluble, forming a green solution, which, when heated to boiling, is decomposed, forming a gelatinous mass.

Citrate of soda dissolves it in considerable quantity, but the best solvent for it is the neutral citrate of ammonia proposed by M. Robiquet, as a solvent for the pyrophosphate of iron. In this salt it dissolves readily, forming a green solution with a brown shade; when evaporated and spread on glass, and dried, it forms scales of a brownish-green colour, which much resemble those of the citro-ammoniacal pyrophosphate of iron. The dry salt dissolves more rapidly in cold water than the pyrophosphate, and has a pleasant saline taste; a solution of it on the addition of ammonia, remains clear, but turns to a reddish-brown colour, while the addition of a portion of citric acid turns it to a lighter green colour.

100 parts of this salt on examination, were found to lose 10 parts of water, and furnish 23 parts of Fe_2O_3 , which correspond to 44 parts of $\text{Fe}_2\text{O}_3 \cdot \text{PO}_5$, the remaining 46 parts being the citrate of ammonia. We have thus a citro-ammoniacal sesquiphosphate of iron, which is a reliable preparation, containing 23 per cent. of sesquioxide of iron, and possessing decided advantages over most ferruginous preparations, on account of its pleasant taste, while it will prove more active than the citro-ammoniacal pyrophosphate of iron, as it contains more iron. We may, therefore, hope that a fair trial of this new salt by the medical profession will gain for it the place to which its composition would seem to entitle it. —*American Journal of Pharmacy.*

PHYSICAL SCIENCE.

On the Effect of Great Pressures combined with Cold on the Six Non-Condensable Gases, by Dr. ANDREWS.

IN this communication the author gave an account of some results already obtained in a research with which he is still occupied on the changes of physical state which occur when the non-condensable gases are exposed to the combined action of great pressures and low temperatures. The gases when compressed were always obtained in the capillary end of thick glass tubes, so that any change they might undergo could be observed. In his earlier experiments the author employed the

¹ Read before the British Association.

elastic force of the gases evolved in the electrolysis of water as the compressing agent, and in this way he actually succeeded in reducing oxygen gas to $\frac{1}{300}$ th of its volume at the ordinary pressure of the atmosphere. He afterwards succeeded in effecting the same object by mechanical means, and exhibited to the Section an apparatus by means of which he had been able to apply pressures, which were only limited by the capability of the capillary glass tubes to resist them; and while thus compressed the gases were exposed to the cold attained by the carbonic acid and ether bath. Atmospheric air was compressed by pressure alone to $\frac{1}{371}$ th of its original volume, and by the united action of pressure and a cold of -106° F. to $\frac{1}{575}$ th; in which state its density was little inferior to that of water. Oxygen gas was reduced by pressure to $\frac{1}{324}$ th of its volume, and by pressure and cold to $\frac{1}{544}$ th; hydrogen by the united action of cold and pressure to $\frac{1}{500}$ th; carbonic oxide by pressure to $\frac{1}{278}$ th, by pressure and cold to $\frac{1}{278}$ th; nitric oxide, by pressure to $\frac{1}{310}$ th, by pressure and a cold of -160° F. to $\frac{1}{380}$ th. None of the gases exhibited any appearance of liquefaction, even in these high states of condensation. The amount of contraction was nearly proportional to the force employed, till the gases were reduced to from about $\frac{1}{300}$ th to $\frac{1}{310}$ th of their volume; but, beyond that point, they underwent little further diminution of volume from increase of pressure. Hydrogen and carbonic oxide appear to resist the action of pressure better than oxygen or nitric oxide.

PROCEEDINGS OF SOCIETIES.

THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

SECTION B.—CHEMICAL SCIENCE.

THE President, Dr. W. A. Miller, F.R.S., &c., Professor of Chemistry, King's College, delivered the opening address.

THE PRESIDENT said that, in the home of Dalton, in the focus of applied chemistry, very few words would be necessary. They could not but remember that, on the last occasion, when the meeting of the British Association was held in Manchester, that illustrious philosopher was still amongst them; and he trusted that the same spirit which actuated Dalton still remained in Manchester to enlighten his native country. Without saying more by way of introduction, he would call their attention to one or two points of progress during the past year. In calling attention to these subjects, he must necessarily refer to debatable ground in science,—but it was in debatable land that progress was necessarily made. He would only touch upon two or three practical applications of chemistry, and two or three theoretical ideas since they last met. The Professor then alluded to the new methods of preparing oxygen and hydrogen, proposed by Deville, which admit of application on such a scale as to allow of the generation of oxygen for manufacturing purposes, and the employment of the oxyhydrogen blast, as a source of heat, in metallurgical operations. The novelty in the preparation of oxygen consists in decomposing by heat the vapour of sulphuric acid, and by a further process, storing up the oxygen in gasholders. The preparation of hydrogen required more care. The metallurgy of platinum had already experienced a remarkable modification, owing to the application of the intense but manageable source of heat obtained by the combustion of these gases.

In connection with oxygen might be mentioned a singular circumstance regarding ozone, which, according to the observation of Schrötter, had been found in a

peculiar species of fluor spar, from Wolsendorf, which, when rubbed or broken, emitted a peculiar odour of ozone.

The active chemist Deville, in following his researches, had discovered a variety of means of obtaining, artificially, crystallised minerals of great regularity and beauty. The methods adopted were chiefly by heating the amorphous substances in a slow current of some gas, such as hydrochloric acid, which was not an unfrequent natural product in volcanic districts.

No discovery, however, had made a greater impression upon the popular mind than that of the remarkable alkaline metals, cesium and rubidium, by Kirchhoff and Bunsen. These eminent men, in investigating the appearances presented by flames coloured by various metallic salts when analysed by the prism, were led, from the appearance of certain bright lines in the spectra, produced whilst they were examining a saline residuum from the waters of the Dürckheim spring, to infer the existence of a substance hitherto unknown. It was found that cesium was present in such minute quantity that a ton of that water, which was the most abundant source of cesium yet known, contained only three grains of its chloride. Taking into account the minuteness of its quantity, and its striking resemblance to potassium, it was not too much to say that the discovery of cesium would have been impossible by any other known method than that which was actually employed. The other metal, rubidium, was somewhat more plentiful; but rubidia also so closely resembled potash, that it would not have been discovered but for the peculiarity of its spectrum.

Referring to the revision of the atomic weights of sulphur, silver, nitrogen, potassium, sodium, and lead by Stas, Professor Miller said that chemist had come to the conclusion that it was not proved that the elementary bodies were multiples of the unit of hydrogen, and in opposition to the opinion of Dumas he had pronounced the law of Prout as imaginary.

Every chemist would read with interest the paper by Graham upon the application of liquid diffusion to analysis. The remarkable conclusion to which the author arrived was that the process of diffusion separated all substances into one or other of two classes, which he distinguished as crystalloids and colloids.

The rapid improvement in the methods of analysis, though not admitting on that occasion of detailed mention, must not be overlooked. A variety of bodies, formerly supposed to be of rare occurrence, were now found in minute quantities, unexpectedly, but widely diffused. The discovery of these small substances was by no means unimportant, for they might aid in solving problems of great interest.

Glancing only for a moment at the important practical subject of the formation of steel, Professor Miller referred to the activity displayed in the pursuit of the organic department of Chemical Science, remarking upon two lines of research as important from their theoretical bearings,—namely, the investigation of polyatomic compounds, and the process of oxidation and of reduction, applied by various chemists, and by Kolbe in particular, to the investigation of the organic acids. The labours of Hofmann upon the polyatomic bases showed completely the principle upon which these bodies might be formed, and he had been enabled to group an unlimited number of atoms of ammonia into one compound molecule. Great progress had also been made in our knowledge of the relations of the organic acids. In conclusion, the President said that Drs. Schunck, Roscoe, and Smith had prepared a Report on the Manufactures of the South Lancashire District, and perhaps few were aware of the large extent to which the science was applied and used in the neighbourhood of Manchester.

In the evening the President gave a lecture in the Concert Hall on "*The New Method of Spectrum Analysis.*"

Professor MILLER said that the subject which the

Council of the Association had desired him to bring before the meeting was one which, amongst the scientific questions of the day, had attracted as large a share of popular attention as any that could be named. It appealed to the imagination so powerfully,—it revealed to us matters of investigation much in the same way as the telescope made known to us what was passing in distant worlds, bringing before us not only those particular changes which appeared to be going on in the bodies which compose our solar system, but it appeared, also, further to reveal to us something of the nature of those distant solar orbs which stud the firmament. Not only, however, did it make known those wonders at a distance, but, like the microscope, it revealed to us also quantities of substances so minute that they would defy any other mode of investigation; it made known to us bodies which not only would defy, but up to the present time had defied, all the sources of analysis and chemical skill. He thought he should best discharge the duty which devolved upon him if he endeavoured to bring before them in an exceedingly brief manner the successive steps by which this discovery had been made. Like all other great discoveries, it was not the work of one individual. It was a work in which, he was proud to say, their own countrymen had taken a prominent part, and many of the members of the British Association had laid the foundations of our knowledge of this point. Newton communicated the first information upon this subject in 1701. We knew nothing of the solar spectrum till Newton revealed it in his great work on Optics in that year, his researches having occupied him many years previously. He would first bring before the audience the spectrum as seen by Newton (not that Newton had the means of producing that artificial light which on that occasion he should employ), gradually bringing them up to the present time. The spectrum was perhaps the most glorious sight the eye could behold.

(Professor Miller then directed a beam of white light upon the wall from an electric lamp, and afterwards directed it, through a prism, to a screen on the platform prepared for the purpose. The beautiful prismatic colours on the screen drew forth indications of approbation from the audience.)

The Professor then went on to say that in the solar spectrum dark lines or bands were discovered by Wollaston in 1801; and the distinguished German philosopher, Fraunhofer, discovered dark lines crossing the spectrum at right angles to its length. Those lines were seen whatever was the material used in the prisms. He would for a moment anticipate his subject by thirty years, in order to show a photographed spectrum on a surface of collodion. This image, it would be seen, was not continuous, but was intersected by bands more or less bright. This he showed in order that his audience might understand what he meant when he referred to Fraunhofer's black lines in the solar spectrum, upon the nature of which much speculation had been exercised. The point next to remember was that other lights than that of the sun also exhibited these lines. For instance, if a solid substance were heated till it gave out light, as all solid bodies would when sufficiently heated, these solid bodies—whether the ball of lime in the oxy-hydrogen light, or the charcoal in the electric light—exhibited broken spectrum, being crossed by bright lines. This led him to several distinct lines of research followed since Fraunhofer. First, the lines in the solar spectra, which he might call cosmical. Next, lines produced by the process of absorption. For the discovery of these lines we were indebted to one of our most illustrious philosophers, who was with them on that occasion—Sir David Brewster. (Applause.) Then there were a series of lights produced by coloured flames. Lastly, there was a series of lines for the knowledge of which they were mostly indebted to Professor Wheatstone—(renewed applause)—the lines produced by the electric spark. Wollaston and Fraunhofer noticed that the electric spark produced spec-

trum, but they went no further. Professor Wheatstone had, however, done so. He had no opportunity of presenting to the audience any of the cosmical lines beyond that he had already shown in the photograph. Sir David Brewster was the first person to throw a light on these lines. He observed that under certain circumstances the sun's rays were absorbed. It appeared certain that particular rays were deepened by the absorbing action of the earth's atmosphere. Then came the beautiful discovery of Becquerell's, in 1842, by which it was made known that there was the same interruption, or black lines, in phosphorogenic rays; and Stokes a few years afterwards showed that the rays which produced fluorescence were interrupted precisely in the same way. But no one had satisfactorily explained the cause of these lines.

He would now lead his audience a second step, for which they were also indebted to Sir David Brewster. He discovered that the dark orange-coloured gas, nitric oxide, had a very remarkable absorptive power upon the sun's rays. This brownish-red gas, placed in a ray of light, and afterwards examined by the prism, showed a series of black bands much more distinctly than those occurring in the sun's light. The moment he put this gas into the course of the ray it produced the black lines. A good many other gases had similar effects. The next point of interest was observed by M. Foucault, who found that by sending the sun's rays through the electric light, we got a black band where the electric light showed a bright one. This led to the discovery which formed the subject of the present discourse. The next step was the discovery of the spectra of coloured flames. In 1822, Sir John Herschel made a series of observations upon coloured lights; and it appeared to Talbot that these observations might be turned to account for chemical analysis. Professor Miller then showed by experiment the observations made by Mr. Talbot upon lithium and strontium, the flames of which were so closely allied in colour that when viewed by the unaided eye but little could be seen to distinguish them one from the other; but the moment they were viewed through the prism there was a marked and striking difference in the bands. Mr. Talbot pointed out that soda and potash gave out very peculiar spectra. It did not matter what preparation of potash was used, the result was the same. In the case of the spectra of the alkaline earths, the lines were very numerous. A map of the spectra [here pointed to] was one published by Bunsen and Kirchhoff; another, going much more into detail, had been published by himself. Passing on to another point of great importance, Mr. Swan, he said, was the first person who endeavoured to estimate the delicacy of these reactions, and he showed that so minute a quantity as the one two millionth and a-half part of a grain of a salt of sodium could be detected by the colour of its flame. Other points also were investigated by Mr. Swan.

The next step was with reference to the spectra of the electric light; and here Mr. Wheatstone gave the first impulse to discovery. In the year 1835, he showed, at Dublin, a map of various spectra produced by the electric sparks passed between different metals, and he discovered the very important principle that each metal had its own peculiar spark, alike whether the electricity employed were voltaic, magnetic, or from the common electrical machine. He further showed these phenomena were not due to the burning of the metals, for he performed his experiments in an air-exhausted vessel, and he put carbonic acid in the vessel and still found the same light. He also examined metals in their melted state, and the spectra of one or two of these the lecturer here showed. The barium spectrum having been exhibited parenthetically, Professor Miller went on to display Mr. Wheatstone's spectra of lead and tin; and he stated that Mr. Wheatstone's investigations had led to the offer of a prize for further investigation, Mr. Wheatstone having been at that time engaged with his electric telegraph. This prize was won by M. Mason,

who published from 1851 to 1855 some important papers on this matter, with engravings of the spectra, giving much more complicated lines than those given by Mr. Wheatstone. Having displayed the spectrum of silver, the learned lecturer proceeded to refer to further experiments made by an American discoverer, and others whom he named. Amongst these were a number of curious observations on the spectra of gases in tubes first filled with these gases, and then as much as possible exhausted. On the table in front of the platform stood an apparatus, consisting mainly of two such tubes, the one containing hydrogen, the other nitrogen, both in imponderable quantities. Electric light passed through these tubes gave, in the one case, a vivid red; in the other, a brilliant blue. It was also found that if two pieces of wire having on them the least trace of lime, or baryta, or soda, were subjected to the electric spark passing between them, the characteristic spectra of those metals were produced. Nobody up to that time had explained the relation of these different facts with the other.

M. Kirchhoff, and simultaneously, Mr. Stewart, investigated the nature of radiant heat, the vibration produced by different degrees of temperature; and both concluded that when a substance was heated it gave out a certain set of rays, which, when cold, it absorbed; or *vice versa*. Having exhibited the light of sodium under the two conditions, to show the contrast, next Professor Miller remarked that the black line in the spectrum before them was the key-note to the whole of Kirchhoff's explanation. The light absorbed there was not lost; it was radiated in all directions instead of being cast on the screen. Kirchhoff proved by theoretical deductions that the dark bands in the solar spectrum were the reverse of the bright bands, and found he could reverse the bright bands, not only of sodium, but of lithium, potassium, barium, and strontium, by putting their flames in the course of the sun's rays. Turning to stellar matters, Kirchhoff had said with great probability that the spectra of Fraunhofer were merely the bright lines which we should see if there were not an intensely heated body in the atmosphere of the sun producing these dark lines. His opinion was that in the luminous atmosphere of the sun, vapours of various metals were present; and that the solid body of the sun behind the luminous atmosphere, emitting rays of all degrees of refrangibility, caused these lines to be observed. Kirchhoff had arranged an extremely sensitive apparatus, by means of which he had been enabled to magnify the solar spectrum in such a way that he could get a spectrum eighteen feet in length, and view every part of it with a microscope. Sir David Brewster and Dr. Gladstone had recently made known the existence of at least two thousand black lines in the solar spectrum, but Kirchhoff estimated them as very much more numerous. Showing them a map of the solar spectrum, Professor Miller said that amongst the lines thus exhibited were a large number corresponding exactly to the lines produced by known metals; and he pointed to and described the drawing of apparatus whereby at once the lines of the solar spectrum could be seen simultaneously and compared with the lines characteristic of mundane metals. Every star had its own series of lines, some of them seeming to show sodium. The sun appeared to contain sodium, potassium, iron, chromium, nickel, and magnesium.

Bunsen, in observing the residue of the water of a certain spring, found spectrum lines which he had never seen before, and supposed them to be due to the presence of an unknown metal, which he afterwards was able to isolate, finding that three grains (only) of it were extractable from a ton of the water. From the beautiful blue lines in the spectrum produced by this metal he named it Cæsium. By the kindness of Professor Bunsen, who had complied with Professor Roscoe's request for a specimen, the lecturer was enabled to exhibit the spectrum lines of this new metal; and Professor Roscoe had also supplied him

with a sample of another new metal thus discovered, and named Rubidium, the spectrum of which he also threw on the screen.

Dr. ROBINSON said he had been deputed to propose a vote of thanks to Professor Miller for the lucid and instructive exposition which he had given of one of the most remarkable discoveries of modern times. As a humble labourer in the same field, he had come forward to express his sense of the high privilege which he had shared with others in hearing those great and magnificent truths so splendidly explained. Familiar as he was himself, from his own researches, with many of those truths, he had never seen them so fully and so beautifully illustrated as they had been that evening. What a wonderful triumph of human intellect it was even to measure the dimensions of the sun; to pass over that vast field that separated him from us, and to weigh that great orb in the balance and to say that it was of such a specific gravity—what a wonderful triumph it was! By the marvellous powers of sight, those powers which linked together for us distant portions of space, it might be conceived that we could pass over that enormous void; but what a triumph it was to say that we could travel there with the understanding—to say that the sun was of such a magnitude, of such a gravity, contained such elements, was composed of such substances, and was a part of our system bound to us by a community of elements! (Hear.) They had that night seen exhibited on the screen those luminous bands which indicated that in the atmosphere of the sun there existed the metals magnesium, sodium, chromium, cobalt, and iron. These were the metals which they knew from other facts pervaded the planetary system. They were found on earth in those mysterious strangers which, under the name of *aeolites*, came down from the planetary space and gave us indications of the common links which bound us together with the other bodies of our system. (Applause.) He concluded by proposing the resolution.

Mr. HOPKINS, the newly-appointed Secretary to the Association, seconded the resolution, which was carried with acclamation, and the interesting proceedings terminated about ten o'clock.

NOTICES OF PATENTS.

Improvements in the Treatment of Vegetable Substances, and in the Preparation of Beverages Therefrom. J. H. JOHNSON. A Communication. (Not proceeded with.)

THE inventor proposes to subject to a kind of desiccating process the leaves, shoots, and other portions of trees, shrubs, and plants, containing tannin or other bitter vegetable principle. When dried, these are to be coarsely pulverized, and used either alone or in admixture with tea, coffee, or any similar substance for the preparation of drinks by infusion or decoction.

In reference to this specification, it is almost needless to remark that, besides having a tolerably comprehensive aim, the novelty of the process is questionable, since the treatment directed is precisely similar to that by which the tea-plant has always been prepared. The production of counterfeit tea from *sloe* leaves, Paraguay tea, and even the old well-known doses of camomile and senna might be advanced as arguments contradictory to the novelty of the suggestion. For ourselves, we should much prefer to accept the cup of tea prepared as a wholesome beverage without the admixture of any sort of medicinal nastiness which might originate with a proposal such as that under discussion—a proposal which fortunately has in the present instance failed in taking practical effect.

Certain Applications of Chapapote and its Products. J. J. DE ARRIETA.

THIS invention relates to the employment, for various use-

ful purposes, of a certain natural matter called, in Cuba, *chapaote*, whether in its concrete, viscous, or more or less fluid condition, and whether alone or combined with other substances. It may be applied as a coating to wood, metal, stone, paper, leather, textile fabrics, fibrous materials, and to a variety of other substances, to all of which it communicates an additional degree of protection not only from wear and tear, and the ravages of insects, but from the destructive action of damp and oxidising influences generally. It may also be employed as a waterproofing material; as an impervious varnish or coating in the construction of air-tight vessels; it serves to strengthen and likewise to ornament wood and other porous and fibrous materials. The *chapaote* is for any of these purposes, applied in its natural condition or in combination with gums, resins, wax, and fatty matters, essential oils, including those produced by the destructive distillation of the substance itself; with gutta percha and India-rubber, spirit and naphtha, hydrocarbons, varnishes, or conjointly with any one of the numerous classes of mineral substances, individually specified. Also with agents for resisting combustion, and other agents and matters.

The comprehensive nature of the specification, of which the above is but an outline sketch, reminds us of the early patents relating to the applications of gutta percha. The significant finale, "and other agents and matters," surely leaves nothing out of enumeration. The West Indian natural product here described, seems to bear a general resemblance both to caoutchouc and to gutta percha, and apparently to be capable of similar application.

Mounting of Tablets or Show-bills, &c. B. G. GEORGE, Hatton Garden.

THE object of the patentee is to produce, at a small cost, an embossed show-card or tablet that will retain its shape notwithstanding the variable temperature and humidity of the atmosphere. By means of a metal die and a counter-die of the pattern or device required, and a printing surface also of the same pattern, the inventor takes first a printed impression upon paper or card; this, thoroughly wetted, is then laid face downwards on the embossing die, and the counter-die then brought down with pressure upon the back of the sheet produces a representation which may be either in relief or *intaglio* at pleasure. A plaster-cast is also prepared from one or other of these dies, which is intended to be used as a backing to preserve the shape of the card, the surfaces being permanently fastened by any suitable adhesive composition, and, if needful, again dried under pressure to ensure perfect contact and accuracy of form.

The mode of proceeding thus minutely described, displays certainly a high degree of ingenuity, and would be calculated to produce a kind of advertising card well adapted for exhibition in our treacherous climate. The additional precautions of varnishing the face of the tablet and of closing, by an after treatment, the pores of the plaster, would no doubt further contribute to the permanent character of the result.

Improvements in the Manufacture of Plate Glass, and in Furnaces employed therein. R. W. SWINBURNE, South Shields, Durham.

THE first improvement refers to the construction of furnaces for melting or firing the materials for the manufacture of plate glass, which furnaces are constructed after the fashion of reverberatory furnaces; but the fire is so placed that the crucible or melting-pot is entirely surrounded with flame. The second improvement consists in a new mode of casting plate glass. For this purpose the patentee constructs a furnace capable of receiving the large pots usually employed in the manufacture of crown or sheet glass. He places these melting-pots at such a distance from each other as will admit one or more

claspers or movable pots to stand between them, and at such an elevation that the brims or edges of all the pots in the furnace are at the same level. The "metal" or melted glass is ladled out of the larger pots into those adjoining, which when filled are removed to the casting-table, whereon their contents are thrown to be rolled into plate glass. The mode of removing them and emptying their contents on the casting-table, is the particular object of this part of the invention. Without entering further into the mechanical details of the specification, it is sufficient to state that the crane or lifting apparatus usually placed above the casting-table is dispensed with, and that cutters or knives for trimming off the edges of the newly-cast plate are superadded to the ordinary equipment.

Improvements in the Manufacture of Manure when Urine is Used. H. PHILLIPS and J. BANNEUR.

IN manufacturing manure when employing urine, it is first collected and stored in vessels, where it is allowed to become decomposed. The construction of these collecting vessels is described as having traps with water-joints, and all the air-outlets provided with an arrangement for holding charcoal or other deodorising material, so that no offensive vapours can make their escape into the atmosphere. It is proposed to convert the stale urine into manure by saturating therein any dry vegetable matter, by preference the ground spent bark of tanners; the materials are allowed to stand in a heap for some weeks, then spread out to dry, and again moistened with the same liquid. This treatment is repeated until the fertilising materials are sufficiently concentrated, and towards the end of the operation it is preferred to employ a small proportion of sulphuric acid in admixture to prevent the escape of ammonia.

There is no doubt that a very valuable manure would be furnished by the process here described; but whether the economy of the process will enable it to compete with other simple means frequently practised on the farm, is a little questionable. The priority of the claim for the employment of charcoal in the air-passages is undoubtedly due to Dr. Stenhouse.

Colouring Matters for Dyeing, &c. M. J. STARK, Norwich.

THIS invention refers to the production of purple colouring matters from aniline, toluidine, cumidine, or any other analogous substances. The patentee converts either of these bases, or any mixture of them, into an organic salt by the addition of an acid, the use of hydrochloric alone, or with nitric acid being preferred. The saline product resulting from the admixture of acid and base is to be diluted with about an equal bulk of water, and gradually mixed with any soluble ferri-cyanide, that of potassium being used by preference. The proportion in which this latter salt is recommended to be employed, amounts to a weight equal to that of the aniline originally taken. After the whole of the acid solution of aniline has been added, the temperature of the liquid is raised to ebullition, and maintained at a boiling heat for a period of one or more hours, varying with the bulk of material operated upon. When the whole has been sufficiently boiled it is allowed to cool, and the greyish-blue precipitate which will have formed separated from the liquid by filtration or subsidence and decantation. This is collected and washed, and while still moist boiled for an hour or so with tartaric or other acid—one part of crystallised tartaric acid to two parts of water—which treatment will have the effect of extracting the brilliant colouring matter from the bulky precipitate; but for the perfect removal of the same, this boiling with acid may require to be repeated. The filtered solution may at once be employed for dyeing purposes, but the inventor prefers to treat it as follows:—When cold it is mixed with ammonia (or with any alkali or alkaline earth) in slight excess by which the purple

dye is precipitated and may be collected by filtration. It should finally be re-dissolved in alcohol or methylated spirit to furnish a dye of a very permanent character, and of a brilliant purple colour, to which the inventor has given the name "chyraline."

This process differs from that originally described by the discoverer, Mr. Perkin, only in respect to the substitution of *ferri-cyanide* for *bichromate* of potassium. Both are oxidising agents, precisely similar in their behaviour as regards their action upon organic bases—thus, in the colour-test for strychnine, these salts are, in conjunction with sulphuric acid, employed almost indiscriminately—so will the products of these patented processes be identical, whether "mauve" or "chyraline," be the name under which the purple dye is introduced to the public.

A Solution of Starch for Volumetric Analysis is prepared by Dr. F. Mohr, by trituration, with concentrated chloride of zinc, and diluting with water; the solution is not clear, but after precipitating the zinc by carbonate of soda, the filtrate is transparent.—*Ann. d. Chem. und Ph.* xxxix. 231—233.

CORRESPONDENCE.

New Source of Rubidium and Cesium.

To the Editor of the CHEMICAL NEWS.

SIR,—The enclosed letter from Professor Bunsen may be interesting to your readers, as it shows in what way lithium is associated with the two new alkali metals in its chief sources, lepidolite and triphyllyne.—I am, &c.

W. STEVENS. SQUIRE.

37, Acacia Road, N.W.

Dear Dr. Squire, — I only returned last week from Switzerland, and, unfortunately, with inflammation of the eyes, which has confined me to a dark room for the last eight days. This is the reason I have not written sooner to thank you for the triphyllyne residues which you kindly brought me, and to express my regret that I was, by my absence from home, deprived of the pleasure of seeing you when in Heidelberg. The residues are comparatively very rich in rubidium and cesium, and contain much more of the latter than of the former, while the residues from lepidolite contain scarcely any cesium. To judge from the reaction in the spectrum apparatus, we ought to be able to prepare eight or ten grammes of chloride of cesium from the whole quantity. Thanking you once more for your kind gift, by which you have put into my possession so rich a source of cesium,—Believe me yours very truly,

R. W. BUNSEN.

Heidelberg, September 16.

Printing Prussian Blue.

To the Editor of the CHEMICAL NEWS.

SIR,—Some time last year I was annoyed to find that, in endeavouring to prepare flame-proof fabrics by the use of a mixture of starch and sulphate of ammonia, the condemnation of the use of this salt by Verreman and Oppenheim was not undeserved, as the iron is acted upon in the subsequent stages of the laundry process. This is not unaccountable; for I have before observed that copper foil, in presence of air heated with sulphate of ammonia, liberates ammonia. Iron does the same. I have seen a beautiful crystalline compound, white, and in appearance like citric acid, containing iron and ammonia and sulphuric acid. Now, I have found that by printing on to cloth, in any pattern, sulphate of ammonia and yellow prussiate of potash it will remain white for any length of time; but upon passing the piece over a hot surface of iron, the printed parts instantly strike blue, especially if slightly dampened. Would not this be available in printing blues and browns on the large scale by iron and copper rollers?

I am, &c. JOHN S. BLOCKET.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

The Chlorides and Bromides of Tungsten.—C. Blomstrand describes (*Journ. für prakt. Chem.*, Bd. lxxxii. s. 408) four chlorine compounds of tungsten.

1. *Perchloride of Tungsten*, WCl_6 , remains as the final product of the action of chlorine (when no oxygen is present) on metallic tungsten or the sulphide, at a strong heat. The vapour is orange coloured. It crystallizes indistinctly, decrepitates on cooling, and is slowly decomposed by water forming the coloured tungstic acid.

2. *Chloride of Perchloride of Tungsten*, W_2Cl_8 or $(WCl_4)_2$, formed probably in small quantity in the preparation of the foregoing compound, and obtained pure by the reduction of that salt with hydrogen. Dark grey like the above, vapour greenish yellow, fuses with difficulty, crystallizes easily, cools without decrepitating, is quickly

decomposed by water with the separation of the blue oxide of tungsten.

3. *Monozchloride of Tungsten*, WCl_2O , or $(2WCl_3 + WO_3)$ is best prepared by gently heating the sulphide of tungsten made in the wet way in chlorine. It is of a beautiful red colour, and crystallizes in transparent needles. It is very fusible; the vapour is orange-coloured. Decomposes in water like the former.

4. *Binozchloride of Tungsten*, WCl_3O , or $(WCl_3 + 2WO_3)$ is formed simultaneously with 1 and 3 in the first stage of the action of chlorine on pure oxide of tungsten. It has a yellowish colour, is vapourised into a colourless gas without fusing, crystallizes in scales, and is decomposed, like the others, by water.

The author also describes three bromides:—

1. *Bromide of Perbromide of Tungsten*, W_2Br_5 , formed by the direct action of bromine on metallic tungsten. It is black, gives dark purple brown vapours, crystallizes easily in distinct needles, decomposes in water, depositing the black oxide.

2. *Monozbromide of Tungsten*, WBr_2O , or $(2WBr_3 + WO_3)$ formed under the same circumstances as the corresponding chlorine compound. Colour resembles that of the preceding salt, but is lighter, vapours brown red, usually crystallizes in perfect needles, decomposes in water.

3. *Binozchloride of Tungsten*, also formed like the corresponding chlorine compound. Ordinarily brass or mosaic gold coloured crystalline scales, infusible, decomposing in water.

The author believes in the existence of a *perbromide*, WBr_3 , but thinks Bonnet's oxybromide— $WBr_3 + W_2O_5$ —apocryphal.

II. ORGANIC CHEMISTRY.

Introduction of Hydrogen into Organic Compounds.—Zinin (*Bulletin de St. Petersburg*, T. iii. p. 529), and Kolbe (*Annal. der Chem. und Pharm.* Bd. cxviii. s. 122), have experimented on the direct addition of hydrogen to organic compounds. The latter digested a hot saturated solution of benzoic acid and a little hydrochloric acid with sodium amalgam, and in this way obtained bitter almond oil, another oil which becomes a crystalline solid on cooling, and a volatile acid. When the action takes place in an alkaline solution, the changes are different. No bitter almond oil is obtained nor the crystalline oil, but more of the new acid is formed, which Kolbe intends to investigate further.

Zinin continues the researches on benzile, some account of which was given at page 223 of our last volume. He there showed that benzile might be converted into benzoïn by the direct addition of hydrogen. He now shows that by continuing the action longer, new bodies may be formed containing more hydrogen than benzoïn. The author made a boiling solution of one part benzoïn and three or four parts alcohol of 75 per cent., and to this he added one part of strong alcohol saturated with hydrochloric acid gas, and then half a part of finely-granulated zinc was slowly introduced into the mixture. As soon as the violent reaction ceased, another half a part of the alcoholic solution of hydrochloric acid gas was added, and the mixture boiled down to half. It was then poured off from the undissolved zinc and mixed with water, whereupon an oily body separated which soon cooled into a crystalline mass which was purified by re-crystallization from alcohol. It was then obtained in rhombic tables, which fused at 55° . This new body is more hydrogenated than benzoïn; but the elementary analysis, the author says, presents unusual difficulties. By the action of nitric acid and of bromine on this new body, other crystallizable bodies are formed.

Bitter almond oil dissolved in the alcoholic solution of hydrochloric acid and boiled with zinc, forms a thick oily body which sticks to the sides of the flask, and on cooling becomes solid and resinous. It is freely soluble in ether,

and from the solution part crystallizes out, the remainder separates as an oily mass, in which, after a time, other crystals form.

MISCELLANEOUS.

Smelting Spanish Iron Ore in England.—Mr. Morrison, of Ferryhill, has just imported a cargo of very fine quality iron ore from Santander, which is said to have proved very valuable in the South Wales district for improving the quality of iron produced from British ores. The ore exists in enormous deposits within a quarter of a mile from the river, and is worked most inexpensively. Many hundreds of tons per week could easily be raised and shipped, and whilst the present low freight continues a profit can be realised upon shipment either to Wales or the North.—*Mining Journal*.

The Oil Wells of Pennsylvania—Curious Spouting Phenomena.—A correspondent of the *United States Railroad and Mining Register*, writing from Oil Creek, Pa., gives some very interesting information respecting the oil wells and the nature of the rocks in which they are found. He states that the yield from the wells has greatly decreased, and that the oil well region, for practical working, is of very limited extent. He says:—"Along the banks of the Allegheny, for five or six miles above the mouth of Oil Creek, and at a point some three miles below Franklin, operations have been and continue quite successful, so that these may be counted among the reliable sources of supply. Beyond them, the Allegheny river, for profitable oil production may be considered dry." The oil in most of the wells is found in a series of sandstone rocks, which are usually met with at about 190 feet below the surface, and the pockets of oil are located in fractures. In many borings, no oil has been found; while in adjacent drillings, which have been pierced into vertical fractures, large quantities have been obtained. Many wells which once yielded twenty barrels per day are now dry. The usual depth of working the wells is 200 feet, but the oil is obtained at various depths. After drilling down 200 feet, a mass of shales 100 feet in thickness is encountered, in which no oil of any account is obtained. At about 325 feet in depth, there is about 40 feet of white sandstone, near the top of which "spouting wells" are found. This is the second oil yielding strata. After passing through this rock, another mass of shales and fire clay is met with; and at 450 feet in depth, another stratum of sandstone, which forms the third oil-bearing series. Here the "big spouting wells" are found, the yield of which is from ten to two hundred barrels per day. These spouting wells are curiosities; they are genuine land whales, and twice as oily as their rival sea monsters. The spouting is caused by compressed gas, and the flow is periodical. One well will flow for five minutes with intervals of ten. Its neighbour will flow once an hour; while one flows four times, and another six times, in twenty-four hours. Again, the ten-minute well will change to a regular flow of three or four hours' duration. Most of them grow gradually less vigorous, and diminish in yield until they finally cease; but some of them stop suddenly.

ANSWERS TO CORRESPONDENTS.

G. F. Rodwell.—Received, with thanks.

R. S.—See Dr. Roscoe's paper read before the British Association, reported in the present number.

John S. Blockey.—The patents referred to in the *CHEMICAL NEWS* for September 7 (page 135), bear the following dates and numbers:—C. H. G. Williams, No. 67, dated January 10, 1861; C. A. Girard, No. 97, dated January 12, 1861; V. Hall, No. 101, dated January 14, 1861. With a view to identification, we propose, in future, to furnish these particulars in connection with every patent coming under our notice.

VOL. IV. No. 95.—September 28, 1861.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Presence of Nitrates in Mineral Waters, and on the Production of Saltpetre, by R. HAINES, M.B., Professor of Materia Medica, Grant Medical College, Bombay.

(Continued from page 155.)

THE existence of nitrates in mineral waters is no new discovery. Berzelius, writing in 1826, gives directions

for the estimation of the nitric acid in them;¹ and H. Rose's "Manual of Analytical Chemistry," published in 1830, describes the method for estimating it, which I attempted to apply.² The proportion, however, that is present is usually very minute indeed, and in the greater number of published analyses it has escaped detection altogether. I have collected together, in the following table, all the analyses I can find on record in which nitric acid occurred in any notable quantity. The number is very small. The quantity of water referred to has been reduced, for the sake of comparison, to the British imperial pint.

Locality.	Saldschütz ³ in ?	Saldschütz ⁴ (Hauptbrunnen).	Flushing, ⁵ in Zealand, Netherlands.	Zwolle in Overijssel, Netherlands.	Svanda ⁶ in Banat, Hungary.	Highgate, ⁷ near old Churchyard.
Well or spring . . .	Spring	Spring	Spring	Spring	Spring	Well
Age or character of strata	Volcanic	Volcanic	Alluvium on Eocene	Alluvium on Eocene	?	Eocene (gravel and clay)
Name of Analyst . . .	Struve	Steinmann	Gunning	Gunning	Ragsky	Noad
Grains of nitric acid in imperial pint . . .	0.781	16.459	1.463	1.120	2.379	4.238

I was struck with the circumstance that the springs which contained by far the largest quantity, arose in a volcanic district.⁸ The similarity in this respect of Aden, actually an extinct volcanic crater, is at once suggested; the trappean formation of the Deccan, in which Nassik stands, is no less of volcanic origin, though under altered circumstances. May we surmise, then, that the volcanic nature of the superficial strata is in some way favourable to the occurrence of nitric acid? Before proceeding to this question, let us dispose of the other instances recorded above.

The occurrence of nitric acid in the Highgate well explains itself. The well is close to the old and crowded churchyard, the organic matter from which, undergoing putrefaction, evolves ammonia, and the nascent ammonia, oxidised by the atmospheric air in the loose earth, is converted into nitric acid. It is a notorious fact that while the deep wells of London, which are sunk through

the London clay, yield an exceedingly pure, though often alkaline water, the water of the shallower wells is generally contaminated with organic matter and nitrates. In the water from the parish pump of St. Clement Danes, in the Strand, which, in accordance with a venerable, but somewhat disgusting ancient practice, was placed close to the churchyard railings, the same thing was observable in a very marked degree. In the springs in the Netherlands, and the Banat mentioned in the table, the nitric acid is not present in any large quantity, and I have no data on which to explain its occurrence.⁹

Nitric acid is not a constituent of any rock masses or strata; it is found in minute quantity in rain water, but, with this exception, there is no doubt that it is exclusively formed at or near the surface of the ground (the production of nitre in the so-called nitre plantations is a notable instance of its mode of formation); hence, the nitrates must be among the first matters dissolved by the rain water as it percolates downwards, while the other salts are more gradually dissolved out at a greater depth. Considering the abundance in which alkaline and earthy nitrates are found on the surface of the ground in India, it is a matter of considerable surprise that they have not been observed more frequently in the water of springs and wells; but this, apart from the limited number and accuracy of observations that have been recorded, may be explained, I think, by the circumstance of their formation at the surface. The fact

⁸ In the list given, in Ure's "Dictionary of Arts," &c., Saldschütz is said to be situated in a volcanic region; I have not been able to discover its precise locality. The most marked volcanic region in Germany is the Elfel district on the Rhine, although a line of volcanic action of older date extends from thence eastward as far as Silosia. (See "Daubeny on Volcanoes.")

⁹ Lyell mentions the existence of no less than "five distinct groups of volcanic rocks" in Hungary, and also that "pumice occurs in great quantity." ("Manual of Elom. Geol.," Fourth Edition, 421.)

is, that, unless the ground is unusually porous, or the fall of rain excessive, these surface salts are not carried down to any great depth; and as the upper surface dries, the saline solution continually remounts upwards by capillary attraction, leaving, by its own desiccation, the saline efflorescence which we observe so abundantly in the drier parts of India; thus the nitrates, for the most part, merely follow this alternating march from a few feet in depth to the surface, and *vice versa*.

But if the concomitance of a large amount of nitric acid with volcanic formations be anything more than accidental, how are we to explain it? Let us enumerate the circumstances which are essential to the formation of nitric acid; they are:—1st, ammonia, or substances capable of producing it, as nitrogenous organic matters; 2nd, oxygen; 3rd, an alkali or alkaline earth, which, by its so-called disposing affinity for the acid, determines the combination. There is a fourth and scarcely less essential condition, the presence of a body which is capable of acting as a medium of combination between the oxygen and ammonia. Now, volcanic products are very rich in alkalies, and, what is more, they are in many instances exceedingly prone to decomposition and disintegration by meteorological agencies, whereby the alkalies become set free. Oxygen is, of course, always at hand. It is not so evident at first sight how volcanic formations can meet the remaining two conditions. Organic matter, as such, they can hardly contain; and, if ammonia is there, it is clear from their origin that it cannot be in the solid substance, but only in the interstices of the fragments or on their surfaces; and I see no reason why this should not be the case, but, on the contrary, much to make it probable. A great number of solids possess, in different degrees, the power of condensing gases upon their surface, ammonia in particular; and when the surface is multiplied by porosity of structure, this condensing power becomes perfectly enormous. The property is most marked in platinum finely divided, as in platinum black, less so in spongy platinum; less again, but still in a very marked degree, in charcoal, and by a decreasing gradation in pumice stone, oxide of iron, alumina, common clay, and sand. Has pumice, then, or pumice-like scoria, such as the loose cindery mass upon which the cantonment of Aden is built, the power of condensing and oxidating ammonia, in presence of the alkali furnished by its own disintegration? The question might be solved by an examination of the well water of pumice-yielding districts. If Saidechütz be, as I suspect, in the Eifel district, this may well be the origin of the nitric acid in the water, as pumice is found in great abundance in the neighbourhood, especially of Neuwied and Andernach, being used as a building stone at the latter place. I am in doubt how far the occurrence of nitric acid in the wells at Nassik can be explained in this way, as it is scarcely probable that porous scoræ are found there. Perhaps, considering how very local the distribution of the nitrates is in these wells at Nassik, and the circumstance alluded to of the quality of the waters being liable to great and sudden variation, the nitric water may find its way from near the surface through open fissures in the rock, which allow it to pass at times with great freedom and rapidity.

Dr. Bradley notices the existence of scoræ on the edge of the crater of the Loonar lake in the Dekkan¹⁰; does the water of the lake contain any nitrate? Mr. Malcolmson states the solid constituents in 1000 grains of the water to be:—

	Grains.
Muriate of soda . . .	29
Sesquicarbonate of soda . . .	4.2
Sulphate of soda . . .	0.1
Potassa . . .	a little
	33.3 ¹¹

But nitric acid may easily have been overlooked. A fresh analysis of this water is much to be desired.

The question of the formation of nitric acid¹² and of the circumstances which favour it, appears to be one of peculiar interest in this country, where the production of saltpetre is so abundant as to give India an almost complete monopoly of the article in the commerce of the world. What connection is there between the occurrence of carbonate of soda in the soil (*Sujee muttee*, or Dhobees' earth) and that of nitrate of potassa? Does carbonate of potassa ever occur in the soil, as carbonate of soda does? I strongly suspect that the greater part of the nitric acid is, in fact, in combination with soda, and that in the rude native methods of extracting the saltpetre, the nitrate of soda is left behind in the mother-liquor, or drains away from the moist salts in the process of carriage. I would urgently recommend a more careful study of the nitre-yielding earths, as, if my conjectures are correct, an immense saving might be the result of the application of a little scientific knowledge; for I am persuaded that the productive power of India, in regard to the nitrates at least, is capable of being extended to many times its present amount.

(To be continued.)

On Atmospheric Ozone,¹³

by Dr. T. MOFFATT, F.R.A.S., F.G.S., &c.

THE mean daily quantity of ozone is greater with readings of the barometer below than above the mean, and greater when the range of the barometer and the number of its oscillations are above the mean. It is greater when the mean-daily and dew-point temperatures are above the mean, but greater when the degree of humidity is below than when above the mean. When the wind

¹¹ *Ibid.*, p. 30.

¹² On the formation of nitric acid, see Liebig's "Chemistry of Agriculture," Part II., chap. viii. and Knapp's "Chemical Technology," I., 356 seq.

¹³ Kuhlmann supposes that, in the formation of saltpetre, when the mixture contains no carbonate of potassa, but only carbonates of lime and magnesia, ammonia is first formed from the nitrogen of the decomposing organic matter; that this forms, with the oxygen of the atmosphere, nitrate of ammonia, which, with the carbonates of lime and magnesia, is decomposed into nitrates of lime and magnesia, and carbonate of ammonia, so that the ammonia is at once the agent in the formation of nitric acid, and of its transfer to the fixed bases. The same observer invariably found ammonia in the crude saltpetre ley, combined partly with carbonic acid and partly with fixed acids. This is also in accordance with the experiments of Collard de Martigny, who found that when milk of lime was kept in a closed and partly-filled vessel, with a little ammonia, and frequently shaken, for six months, nitric acid was formed. Longchamp (*Ann. Chim. Phys.*, xxxiii. 5; xxxiv. 215) maintains that nitrogenous organic compounds contribute nothing to the formation of saltpetre; but that the water contained in porous substances, such as chalk, absorbs oxygen and nitrogen from the air, and condenses them into nitric acid. The experiments of Gaultier de Chanbry (*Ann. Chim. Phys.*, lii. 24), according to which great quantities of nitrates are found in limestone hills, which contain but a mere trace of organic matter, favour this view. It may, however, be admitted that, under certain circumstances, as in electrical discharges in the air, the nitrogen, the nitric acid, and the carbonate of ammonia of the atmosphere, contribute to the formation of saltpetre, without denying that, in ordinary cases, the nitrogen of the organic matter plays the principal part. (Gay Lussac.—*Ann. Chim. Phys.*, xxxiv. 56; compare Fontenelle, *Journ. Pharm.*, 14), Gmelin, "Handbuch der Chemie," 4te Aufl. I. 302.

¹³ Read before the British Association.

¹⁰ Carter's "Geological Papers of Western India," p. 766.

is from points of the compass between N.W. and S.E. by N. above the mean number of times, ozone is at its minimum, and when it is in point S.S. of these above the mean number, it is at its maximum. It is also at its maximum when the wind is above its mean force. When rain is above the mean quantity ozone is also at its maximum, and also with hail; but the quantity is smaller on days with snow and sleet than on days without them. With fog it is below the mean quantity. It is above it with cirri, halos, aurora, and the zodiacal light, but below it with thunder, thunder and lightning, and thunder storms; and it is at its maximum with negative, and minimum with positive electricity. The mean daily quantity is greater with decreasing than with increasing readings of the barometer, and it is three times greater with wind in points S. of E. and W., than it is in points N. of these,—the greatest quantity (3.5) with S.W., and the smallest (0.8) in the N.E. points. Ozone periods may be said to commence invariably with decreasing readings of the barometer and increase of temperature, and with winds from S. points of the compass; and to terminate with increasing barometer readings, decrease of temperature, and wind from N. points of the compass. These results are from 296 periods. By far the greatest number of ozone periods commence in S.E., and a great majority terminate in N.W. points. Indeed, although the commencement of ozone periods in N.W. points is not uncommon, the S.E. may be called the points of their commencement, and the N.W. the points of their termination. The quantity of ozone is greater in the night than in the day. It is greater with new and full moons than with the first and last quarters, and it also varies with the seasons. It is greater in January, February, and March, than in April, May, and June; but greater in the latter months than in July, August, and September. In these it is at its minimum, and it again increases in October, November, and December. The greatest quantity is in April (2.3) and December (2.4), and the smallest in July (1.3) and August (1.3). The greatest number of ozone days is in April (25), and the smallest in August (29) and November (17). Whatever tends to a deflection in the direction of the wind leads to a corresponding result in ozone observations, and a town, chemical works, drains, and cesspools, in fact, at any locality, in which the products of combustion and decomposition are in sufficient quantity to decompose ozone, the air will be de-oxygenated, and the wind or current passing over it will be non-oxygenated. The quantity of ozone increases with increase of elevation above the level of the sea. The following results were obtained from observations taken at fifteen stations along a tidal river and its estuary. The stations varied in height from three feet to six hundred feet; and in distance from the river, from its bank to eight miles inland. Some of the stations were in towns and villages; from these we find that ozone, as a rule, increases with increase of elevation, and decreases with increase of distance from the river; and that it is invariably in greater quantity in the open country than in towns and villages. This, I believe, is a universal law. It is the same on the Alps as at lower elevations. The following results I obtained from observations forwarded to me by a member of the Alpine Club. The observations were taken at elevations varying from 740 to 8000 feet. The mean daily quantity of ozone from 740 to 2000 feet is 15; from 2000 to 4000, it is 33; from 4000 to 8000, it is 77. [The degree of humidity at the lowest elevation was 58; at the next, 83; and at the last, 83 also.] Ozone is a highly oxidized body, and it is easily

decomposed by oxidable substances. If a test-paper prepared with iodide of potassium be freely exposed to the air in a locality where the quantity of these substances is at a minimum, it will in time become deeply coloured brown, and ozone will be said to be at its maximum. If a similar paper be placed in a locality where the quantity of oxidable substances is at a maximum, as over or in the neighbourhood of drains and cesspools, the paper will remain uncoloured, and ozone will be at its minimum; and if the slip that becomes brown be placed in the latter place, it will lose its colour. In the first condition the ozone oxidizes the potassium and sets the iodine free. In the second, the oxygenated air meets with incompletely oxidized substances, which are more easily oxidable than the potassium; and in the third instance the brown colour of the paper is removed by sulphuretted hydrogen. The ocean, with the wind that blows over it, is represented by the first condition, and the land, with its wind bearing the products of combustion and putrefaction, by the second and third conditions. The conditions of an ozone period are undoubtedly those of the south or equatorial or ocean current of the atmosphere, and those of a no-ozone period are as clearly those of the north or Polar or land current. With the former we have low readings of the barometer, with the maximum of its range and oscillations increasing mean-daily and dew-point temperature, maximum of rain, prevalence of cirri, halos, and high winds, with negative electricity; with the latter we have high readings of the barometer, minimum of range and oscillations, decreasing temperature, no halos, no cirri, low winds, settled weather, and positive electricity. The atmospheric conditions, with ozone and those with no ozone, are so invariable, and ozone periods so frequently commence and terminate with S.E. and N.W. winds, that the points of the compass might not inaptly be arranged into four sets—viz., the equatorial or ozone points, the Polar or no ozone points, and the transition points, the south-east, the points of transition from the north or Polar to the south or equatorial, while the north-west are those of change from the latter to the former. In a medico-meteorological sense I am not prepared to state that atmospheric ozone produces any form of disease, but I have no hesitation in saying that it prevents diseases of the epidemic character, by removing their causes. The maximum of diseases undoubtedly takes place while the oxygeniferous current has the ascendancy, but they are of a sporadic nature, and are caused by the vicissitudes of weather, electrical influences no doubt playing an important part. The maximum of deaths takes place while the wind is in N. points. By far the greatest number of diseases, however, take place in the N.W. and S.E. points, or at the commencement of ozone periods, and these are chiefly affections of the nervous and muscular systems, from which it would appear that derangements in the nervous and muscular forces take place at the time of transition from the no-ozone and positively electric to the ozone and negatively electric current of the air. The diseases peculiar to the calm, which is also a no-ozone condition, are of an epidemic nature, such as cholera and choleraic diarrhoea. These results are deduced from 2727 cases of disease and 1149 deaths which occurred at Hawarden in a period of ten years. As the S. is the higher and oxygeniferous current, and the N. the lower and no-ozone current of the atmosphere, in a medico-meteorological sense there ought to be some analogy between the higher strata of the atmosphere and the S. wind and between the lower strata and the N. wind, and observation shows that as

regards ozone and deaths they are similar. All who have paid any attention to the atmospheric conditions of a cholera period must have observed that the readings of the barometer are remarkably high, that they slowly attain their maximum, and that when they begin to decrease they as slowly approach their minimum. While the barometer is increasing, the wind continues to veer from N. to N.E. and E., until there is a perfect calm. At first the air is clear and the sky cloudless. The air becomes less clear, it thickens to haze, and the sky can no longer be perceived. There is no ozone, and the brown test papers rapidly lose their colour. At the commencement of the calm there are a few cases of diarrhoea, and as it continues cases take the character of choleraic diarrhoea, and at last a few cases of cholera occur. The calm continues, the haze thickens, and the cases of cholera *pari passu* increase in number and severity. The haze becomes a dry fog, things communicate a gluey sensation to the touch, insects fly about in swarms, and the epidemic reaches its height. The barometer having reached its maximum, begins gradually to drop, the haze becomes more of the character of fog, and if it can be seen through cirri will be seen hovering in the higher regions of the air, or moving slowly northwards. The south current is now approaching, the barometer continues to fall, a gentle motion of the air is perceived from S.E. Ozone is detected; there may be rain; there may be a thunderstorm. The wind increases in power and ozone in quantity, and cholera disappears. The rationale of this medico-meteorological process is this: The first part of the process was the north current gaining the ascendancy; and, as it is the land current, bearing the products of decomposition, ozone is reduced to its minimum. While the air keeps in motion these products do not accumulate in great quantity. The barometer begins to drop. The north current falls back, and is succeeded by the calm. The products of putrefaction go on accumulating; there is no renewal of air, and sulphuretted hydrogen can now be detected. Cholera cases go on increasing as the poisonous substances accumulate. As the barometer decreases slowly, the south current slowly advances; but that it is advancing is shown by the cirri in the higher strata of the air. The air becomes more moist, because the moist current is approaching. The south or ozoniferous current at last gains the ascendancy, and cholera vanishes, because the incompletely oxidised bodies, the poisonous substances—perhaps hydrocarbons—are rendered innocuous by the ozonised air affording them oxygen. These views are supported by the facts that diarrhoea and choleraic diarrhoea are most common in the autumn months, and then ozone is at its minimum, and that ozone is invariably absent during cholera periods. Cholera is also observed to advance from east to west; so do the Polar current and the calm. I may state, also, in support of these views, that during the cholera epidemic at Newcastle, in 1853, the calm prevailed and ozone was at its minimum. From the 24th of August to the 11th of September, 1854, ozone was only once perceived, and then in a minimum quantity. Cholera was then at its height in London. On the 10th of September I wrote to a friend, stating that the S., or ozoniferous current was approaching, and requested him to watch its effects upon the epidemic. On the 11th we had a S. wind, with ozone, and from that day the number of cases of cholera diminished. In conclusion, I have to observe that in making ozone observations the test paper ought to be kept in the dark; that sulphuretted hydrogen, ammonia, and moisture cause loss of colour.

Dr. ANDREWS said that in order to determine the nature of the body said to be ozone, it should be ascertained that it possessed all the qualities of ozone. He had found many difficulties in his researches on the subject; but so far as his own opinion went, he was inclined to believe that what Dr. Moffatt spoke of was ozone. A very simple method of discovering it was to expose a piece of paper, moistened in a solution of the hydrate of potassium, to the atmosphere; if there was any ozone in the air the paper would soon become coloured. It was very interesting to expose these papers at different places for the same length of time, and the depth of discoloration would give the relative quantity of ozone in the air. He thought it was important to find out the causes of the destruction of ozone in the atmosphere, because it was quite clear that the power of destruction was as actively at work as the power of its production. Of all the tests of ozone, he thought the most delicate was that of metallic mercury.

Dr. R. ANGUS SMITH said he had occasionally made experiments with ozone, and he could confirm the observations of Dr. Moffatt as to its absence from large towns. He had never yet found that ozone approached Manchester within half-a-mile. The test which had been mentioned was a very valuable one. He did not mean to say that the effects were caused by the existence of ozone, but it was very important as an indication of the state of the atmosphere. He therefore hoped Dr. Moffatt would continue these observations, as he was sure he was on the right track. There had been several objections to these observations on ozone made by chemists, who contended that the indications were referable to the acidity of the atmosphere. From the absolute non-existence of these indications in Manchester, he could not refer them to acidity, because the rain of Manchester was nothing less than diluted vitriol, many hundred tons of vitriol falling upon our heads in Manchester in the course of a year. (Laughter.)

Mr. J. GLAISHER, F.R.S., said this was a question to which he had paid particular attention since 1848. He obtained test-papers from Dr. Moffatt, and he placed them at Greenwich Hospital, on the banks of the Thames; at the Greenwich Royal Observatory; and at Blackheath. The results were, that the papers were never coloured at the Hospital, whilst they were frequently coloured at the Observatory, and always coloured on Blackheath. From his investigations into ozone, he had learned to be careful in his deductions. He pursued his investigations at different hospitals, and placed the papers over several of the cholera patients, and when the papers were returned to him, he found several were deeply coloured, whilst others were uncoloured. He found, however, that where there was no colouration there was the greatest number of deaths. There was no indication of ozone whatever at St. Thomas's Hospital, or, in fact, near the Thames, except on occasions when the wind was moving there would be a slight tinge on the paper. His next discovery was that there was more ozone by the sea than inland,—about four times as much. In towns there were seldom any indications of ozone. As to height, ozone increased with elevation, or the purity of the air. Ozone was destroyed by the exhalation of animal matter in these districts. He agreed with Dr. Moffatt in all respects but one, and that was with regard to the barometer; for he had never yet been able to trace any connection between the variation of the barometer and the health of man. He agreed with Dr. Moffatt that a wind off the sea produced a maximum of ozone, but he did not think it was produced by any particular wind blowing

always in one direction. Taking Dr. Moffatt's researches altogether, they had been a great assistance to him (Mr. Glaisher). He was sure Dr. Moffatt was in the right path, and he hoped he would continue untiring in following out his present results.

Dr. DAUBENY said that the observation that there was a great deal more oxygen in the neighbourhood of the sea than in the interior of our island, was quite in accordance with the theory that the ozone was destroyed by animal and vegetable exhalations. He might take this opportunity to produce a specimen of fluor spar from Bavaria, which, if rubbed, appeared to contain ozone. He should like to know if it was a fact that there was an entire want of ozone on the top of the Alps.

Dr. MOFFATT said that, with regard to the barometer, he did not know that he could attribute disease either to the high pressure or low pressure of the atmosphere; but he believed it was the change from one pressure to the other that caused disease. That might be electric. Both the animal and vegetable kingdoms could adapt themselves to several inches of pressure, but it was the change from one pressure to the other which caused the disease,—whether it was electric or moisture he did not know.—In reply to a question as to what the test-papers were made of, Dr. Moffatt explained that they were made of iodide of potassium, starch, and water. It was difficult to make two packets alike, and the best way would be to purchase them of Negretti and Zambra.

TECHNICAL CHEMISTRY.

*On Bleaching,*¹ by Mr. HENRY ASHWORTH.

THE art of bleaching may be considered to have taken date from the earliest ages, probably from the time when human knowledge had become extended to the fabrication of clothing; and the inventor may have been the first housewife whose personal feelings induced the desire to enjoy the comeliness and the comfort of clean linen. Primarily, the operation has been accomplished by soap and water, the friction of the human hands, and exposure to the whitening effect of the atmosphere. Theoretically speaking, the bleaching of the present day, in all its enlarged proportions, is accomplished out of the same elements, although in their application they may have been altered or modified to suit the economy of modern chemistry, and the mechanical appliances which now supersede the manipulations of a by-gone age. The interesting character of the progress of these changes it will be our province to endeavour to trace. The ancient writers do not appear to have left us any details on the subject, and the knowledge we possess extends only as far back as the middle of the last century. Previous to that time, the cotton manufacture was scarcely known, and the linen manufacturers of the North, who knew nothing of bleaching, used to send their brown fabrics to be bleached in Holland, and they were received again in the course of eight months, and sold under the definition of brown Holland. In the year 1749, the practice of lime bleaching was introduced, and the cloth was then steeped in alkaline lye, which was called "bucking." The subsequent process of bleaching was done by exposure on the grass, which was called "crofting," and these operations were repeated five or six times, extending over a period of eight or ten

weeks. The first advance upon this tedious process was made by Dr. Home, of Edinburgh, who substituted a very weak solution of sulphuric acid for the buttermilk, the rye meal, and the bran operations previously employed, and by this means he accomplished the same result, and in a shorter time than by the buttermilk process, which had required two months. In the year 1787 an important change took place in consequence of the discovery of M. Scheele of Sweden, of a chemical compound, such as is now designated chlorine, and this was used as a substitute for exposure to the atmosphere. The repeated experiments of Berthollet added considerably to the facts already known; but the practical effects of these discoveries were more fully brought out by Mr. Watt and Dr. Henry, and it is to them that the chief merit is due of introducing the new mode of bleaching cotton goods. To those who are familiar with the history of the cotton manufacture, it will be apparent that bleaching, as a distinct pursuit, had by this time become a necessity of the trade, therefore the manufacturer consigned to the bleacher, who was originally called a whitster, his woven fabrics in the state in which they came from the loom, loaded as they were with impurities; and the following is described as the course of operations by which he undertook to whiten them. The loose fibres of cotton adhering to the surface of the cloth were removed by passing the whole length of the piece over a curved plate of iron heated red hot,—an operation that required to be done with great velocity to prevent any injury being sustained to the goods. The cloth was then deposited in a cistern of water, or in a weak alkaline lye, where it would remain, perhaps for some weeks, until the flour paste, used as dressing by the weaver, had become softened by fermentation. The removal of the paste and other matter contained in the web was accomplished by the agitating process of a dash wheel, or cylindrical box revolving on its axis, having four compartments or internal divisions radiating from the centre, in which the bundles of cloth were deposited. A supply of water was being injected at the sides of these compartments to carry off the impurities as they were liberated by the jolting concussions created at every revolution of the wheel. This invention was deemed a great advance upon the previous practice of dragging the pieces by hand through a stream of water in the water pits constructed for the purpose. The cloth was next boiled in lime water, and another operation of the dash wheel succeeded. The lime water had to be expressed from the cloth by passing the whole length of each piece betwixt a pair of revolving rollers called "squeezers." It was then immersed in a composition called "chemical," and when taken out was carefully washed in cold water. These operations, more or less varied in their character and arrangement, were repeated a number of times; the cloth had some weeks of exposure in the grass fields, with an occasional sprinkling of water to aid the process of whitening, and was then considered to have received a bleaching; the process of drying was in long sheds, constructed mostly of wood, having openings at the sides with sliding doors; and the pieces were suspended by hand upon lines of railing until they had become sufficiently dried by the atmosphere. When taken down, every piece was neatly folded and compressed by screw pressure, and this was deemed the finishing process before delivery at the warehouse of the manufacturer.

It is from such a beginning, and within living memory that we shall endeavour to trace the successive changes which, in the course of sixty or seventy years, have led

¹ Read before the British Association.

to the establishing of that important branch of trade, now so intimately connected with the cotton manufacture of this and other countries. The chemical preparations originally adopted were somewhat primitive: the acids were derived, to some extent, from an immersion of the cloth in sour milk, although the use of a weak solution of sulphuric acid was the more prevailing practice. The alkali which is the basis of soap was derived from the ashes of burnt fern, sea-weeds, or other similar products. The oxygen of the atmosphere was employed to whiten the grey fibre of the cloth, and a decoction of sorrel was used to remove the stains and iron moulds. About the year 1795, it had become obvious that the growing demands of commerce required a more efficient agency than could be derived from such rude elements. Severe pressure on the trade was felt from the enormous amount and cost of labour required, the heavy expense and the inferior quality of the drugs then in use, the rental paid by the bleacher for so large an extent of grass land as he found it necessary to occupy with the exposure of his cloth to the atmosphere, together with the unavoidable delay, uncertainty, and pecuniary losses, which were constantly occurring from unfavourable weather and other causes. The manufacturer also suffered greatly from the frequency of his disappointments, and the inconvenience and loss he sustained from the necessity of having his capital in goods lying three months in the bleach grounds. The emergency which had now become so apparent had the effect of bringing out inventions and improved processes. These succeeded one another with great rapidity, and those proprietors of works who possessed intelligence and capital made rapid progress; although there were other instances in which the want of capital or the absence of enterprise prevailed, and in these cases there remained a lingering adherence to those antiquated usages which were being superseded in other concerns. Every one knows that in whatever manner bleaching is done, it must be effected by means of true chemical agency; and therefore it was to the chemist that the bleacher had, in the first instance, to look for the discovery of more potent agents to effect his object.

The first great triumph in this department was the discovery, in 1798, by Mr. Tennant, of Glasgow, of a method of making saturated liquid chloride of lime,—an article which was found to answer quite perfectly all the purposes required by the bleacher. This invention, for which he took out a patent, consisted in the substitution of lime for potash. His patent right was resisted by the bleachers of Lancashire, and was set aside by the verdict of a jury. The grounds of this decision were, that the patent included a mode of "bucking" with quicklime and water, which was not a new invention; and because one part of the patent was not new, the whole of the claim must be set aside; and by this decision the use of liquid chloride of lime in bleaching was thrown open to all. It was deemed an unfortunate circumstance that, in consequence of an error of expression in describing his process, Mr. Tennant should be deprived of the fruits of a laborious investigation, extending over several years. There was a strong feeling of sympathy manifested, and the bleachers of Lancashire presented him with an expression of their grateful acknowledgment by a service of plate, which Mr. Tennant accepted; but it was most in accordance with the character of his original design to press onward with his discoveries, and to bring his first invention to a still more practical issue. He, therefore, adopted a new method,—one which at length he completed and

secured by patent, for impregnating quick lime in a dry state with chlorine, and in this instance his right remained uncontested. He lived to enjoy his pecuniary reward; and the manufactory which he established in Glasgow is at this time the largest in extent of any of the kind in Great Britain. The supply of alkali, which was being derived from the burning of fern, and from the incineration of sea-weed on the coasts of Scotland and Ireland, having become insufficient, it was supplemented by the importation of barilla, an article produced in the same way upon the coasts of Spain, Sicily, and Sardinia. The alkali procured by such means was very crude and very unreliable in its action, and the use of it was at length superseded by potash obtained from the clearing and burning of forests in the United States. At length the consumption of the article had become so greatly enlarged, and the price so enormously high, that the demand for the production of alkali became an object of mercantile attention. Chemical science stepped in, and very quickly responded to this appeal on the part of the bleachers. The consequence was, that an artificial soda was invented, called "soda ash," or British soda, which, in regard to cheapness and efficiency, has caused the bleachers to dispense with the use of potash; and the quality of the article has so successfully commended itself to the consumers, that the manufacturers are now annually exporting British soda of the value of one million sterling over and beyond the requirements of the bleachers, soap makers, and glass manufacturers of our own country. It is worthy of remark that the great bulk of our shipments of British soda are to the United States, from whence, only a short time ago, we were importing very large quantities of potash, the production of their forests. Thus, by an art which half-a-century ago was almost unknown, and by the agency of our coal as fuel, we have succeeded in converting certain products which we dig from under our feet, such as salt, pyrites, and lime, into one of the most important branches of manufacturing chemistry. These discoveries in chemistry may appear extraordinary, although they are not more important in the economy of bleaching than are the mechanical arrangements which have superseded the exposure of labourers, in all states of the weather, to the accustomed drudgery of the "crofters" of old. The "crofters," of whom we have spoken, bore the appearance of remarkably strong men; their working dress was of thick white flannel, called "gladding;" the cut of the coat was peculiar, having a loose, open appearance, and a low, flat collar, on which the shirt collar usually rested. They had their necks uncovered; and, their employment being so much exposed to moisture, they seldom wore stockings. Altogether, they assumed a bearing of unconcern about the state of the weather, and were quite regardless of the splashing of water. Their employment consisted mainly in the handling of wet cloth, and in removing it, either by hand or by wheelbarrows, from one operation to another. Perhaps the most distressing part of their labour was that of carrying upon their shoulders a pile of wet cloth, rising to some height above the head, which they conveyed to some considerable distance in the fields, and spread upon the grass. In the severity of the winter season there would be drippings from the cloth, forming icicles, which would be adhering to the skirts of their clothing. It has been through a succession of mechanical inventions that these laborious operations have been dispensed with, and, one after another, they have been handed over to the power of the steam-engine. The machinery of the dash-wheels are in a great measure

superseded; the use of wheelbarrows for the removal of cloth from one operation to another are not now required; the suspension of wet pieces upon wood railing in an open shed for the purpose of drying has passed away; all this work is now done under cover; the drying process is carried on in heated rooms; and the suspension of the cloth is accomplished by an ingenious application of machinery. Practically speaking, bleaching operations have been revolutionised; and probably the most efficient labour-saving invention has been a mechanical arrangement, or, as it is termed, a continuous system of cloth working. By this method, it is not now necessary to conduct the bleaching of individual pieces singly, one by one, but to have the ends of them sewed together by hundreds in a consecutive string, and have them drawn through a number of operations in their ordinary succession; the regularity of the work being attended to by boys, and the superintendence by men. It will be obvious that, by the various means referred to, the operation of bleaching has been much simplified, and the expense reduced; but, meanwhile there have been great changes, and eventually an increasing demand for what is usually termed "finish," which consists of a skilful application of calendering, pressing, rolling, and otherwise rendering a piece of plain cotton as near as possible in accordance with the design of the manufacturer or the exporter, who may undertake to gratify the taste of the consumers in the various markets of the world. To such an extent has this rivalry or competition by "finish" been carried, that the machinery, labour, skill, and cost of extraneous materials required, have occasioned an expenditure that is said to exceed all the other expenses previously incurred in the bleaching. Dyeing has also been associated with bleaching and finishing; and the class of goods which are embossed and figured by pressure now belong to this department, and afford another variety in the attractions of cotton fabrics. The result has been that the time required for the operation of bleaching is now about as many days as formerly it required weeks to accomplish. Honour to British genius that these advantages have been derived to our country.

The general public will no doubt feel curious to ascertain whether any and what proportion of the money saving thus effected has reached the consumer; some other portion of the public will inquire to what extent the advantages thus achieved by science and art have been shared by the operative class employed? It is not expected that much concern will be manifested about the interests of the proprietor, and it is not unreasonable to suppose that a still more minute inquiry will be raised about the "human machine," more especially, whether, during the progress of these advances in manufacturing art, the material, moral, and intellectual condition of the working class has been made to keep pace with all these improved manipulations, which, amidst the struggle of changes, have destroyed the character of many employments, but have greatly increased the whole number of persons employed? These inquiries it will be our endeavour to satisfy. The advantages shared by the consumer will easily be reckoned. We have before us a printed card, or list of prices for bleaching issued by a leading firm in the year 1803. At that time the charge for bleaching a well-known description of cloth was 7s. 6d. for a piece of 28 yards, and it is now 6d. The case of the labourers employed in bleaching 60 or 70 years ago was, as before stated, a very harassing one; they suffered severely from exposure to wet and cold, and, as a consequence, from rheumatism and asthma. The earnings of a "crofter" would be from 10s. to 15s.

per week. Upon wages so scanty, and with some uncertainty of employment, their mode of living was necessarily inexpensive. Oatmeal was the staple commodity of their food. They used it as porridge; their bread was of oatmeal, either in leavened oat cakes, or baked in the form of a loaf called jannock, which is said to have been introduced by the refugee Flemings; and animal food, with the exception of bacon, was seldom found at the working man's table. Now-a-days, the workmen in bleach works perform all their work indoors, and are, therefore, no longer exposed to the coldness and moisture of the former period. Their wages are increased in a proportion which cannot easily be estimated, and their employment is one of great regularity. They have nearly ceased to consume oatmeal; jannock is unheard of; oat cakes are seldom seen; and their tables are now spread with wheaten bread, animal food from the shambles, and all the other articles which usually enter into the consumption of families in the other grades in life. The social condition of the operative bleacher of early times cannot easily be separated from the rest of the working population of that day, neither could they now be described in any other manner than that which would apply to the operatives around them in other pursuits. We may refer to their mode of pleasure-taking as affording in itself a very appreciable indication of the past and present. The amusements which formerly prevailed were rude and boisterous; now they are more refined and intellectual. Bull-baiting, bear-baiting, and cock-fighting were amongst the common amusements of the day, especially at the wakes and fairs. The game of foot-ball was a very favourite one, so much so that the people of one place would make selection of their combatants and have them pitched against those of some other place, and these would contend in very ardent strife for the renown of mastery. Indeed, so very popular was this game, that a match at foot-ball was, upon one day in the year, tolerated by the inhabitants in the streets of Bolton. The whole of this is now given up. The game of cricket is becoming a popular one, and others equally harmless in their character are being introduced. Their manners have been designated by the historian as "frank and primitive." Therefore, upon such a foundation of industry as that already described, and with elements of character admitted to have been generous and progressive, it will not be matter of surprise to discover that at the present day a commendable position has been attained by this class. Provident Institutions are becoming numerous, and upon holiday occasions the members are fond of the imposing effect of a display of their numbers and respectability. The parade of their flags and other official insignia sometimes disclose a designation of the body which, amongst a manufacturing class, may appear somewhat grotesque, such as Druids, Odd Fellows, Gardeners, Foresters, and the like. There are a great many depositors in the savings-banks; the co-operative societies have absorbed no small amount of their money savings, and the more intelligent have been engaged in the conducting of mercantile pursuits of these concerns. Perhaps there is no other illustration of the spirit of progress so comprehensive or so pregnant with results of a promising nature as the following:—Manchester, which is the industrial centre of the cotton manufacture, is also the centre of 127 Mechanics' Institutions, associated together as the Lancashire and Cheshire Union. The inquiring mind, when put in motion and stimulated by example, is sure to take a direction resulting in intelligence. Hence, among other means, they have

recourse to cheap trips by railway to some distant part of the country. The Lancashire operative does not fail to see that those who are but little above him in station have their autumnal excursions. He works hard, and why should he not shake off, for some short period at least, the burden of wear and tear of body and mind, and transport himself, with other members of his family and friends, over some other portion of the earth's surface which he has not seen, and share the healthful recreations and the pleasures attainable in modern life? Moreover, by an excursion he falls into the way of new scenery, new faces, strange remarks, historical associations, and observations of other trading pursuits to which he has not been accustomed, all tending to enrich the mind, gratify the senses, and create new impressions of delight. In this way the traveller, whose mind is open to profit by what he sees, returns home instructed, and at an expense so slight as to make no conceivable inroad upon his savings fund.

Seventy years ago Sunday-schools had made but slight progress. There were but few persons who could read, still fewer who could write; and when anyone received a letter, he had to carry it away, perhaps a good many miles, to find a scholar who could read it. At the present time, Sunday-schools abound, day-schools are numerous, and the affair of carrying away a letter in search of a scholar may now, with much complacency, be put down as among the reminiscences of seventy years ago.

On the Action of Water on Lead,¹ by Dr. F. CRACE CALVERT, F.R.S.

I WOULD not have troubled this Section with bringing before them a subject which has been noticed by them several times already, if these researches (which were made in connection with a Select Committee of the Sanitary Association of this city) had not presented some interest on several points,—namely, the action on lead of a water supplied to a large population; the determination of the quantity of lead that the same water took up in a given length of time; and, further, with the hope of removing from the minds of some chemists the impression that soft surface water does not act upon lead.

These experiments have extended over a period of more than twelve months, and above 300 samples of water have been tested, and led to the following conclusions:—

First, that the water supplied to Manchester, and passing through a lead pipe used as a supply-pipe, was for four days highly charged with lead compounds, and that the quantity gradually decreased for six weeks, when the water ceased to absorb lead. But if, during that period, the water were allowed to remain in contact with the pipe for twelve hours, its action was still very marked, and it may be stated that, at the end of six weeks, the water still contained $\frac{1}{10}$ th of a grain of lead per gallon, and after three months $\frac{1}{30}$ th of a grain was found.

Secondly, experiments were made on five samples of piping of the following description:—No. 1, extra tinned lead piping; No. 2, ordinary tinned lead piping; No. 3, best or virgin lead piping; No. 4, common lead piping; No. 5, block tin piping. The water was left in contact with these pipes for twelve hours, and, with the exception of the one last mentioned, all were acted on, the

proportion of lead taken up by the water from the lead pipes amounting to from $\frac{1}{10}$ th to $\frac{1}{30}$ ths of a grain per gallon. Waters containing these quantities of lead per gallon are quite sufficiently charged with that compound to prove injurious to health if used as a beverage. I may substantiate this statement by the fact that four samples of water, which I have lately examined as having injured the health of the inhabitants of this city, contained from $\frac{1}{10}$ th to $\frac{1}{30}$ ths of a grain of lead per gallon. Therefore, there can remain no doubt that the water of this city may become sufficiently charged with lead to injure the health of the inhabitants.

Dr. Crace Calvert concluded his remarks by stating that, on allowing water to remain for some time in the pipes, and then again bringing them into constant use, the action of the water on the pipes is greatly increased.

In the discussion which followed,

Dr. SMITH, of Sydney, said, from experiments he had made at Sydney, he found that the action of water upon pipes made of lead and tin was much greater than its action on lead alone.

A Gentleman said that he had found that the water of Sheffield, which came from a similar source as that of Manchester, was strongly contaminated by passing through lead pipes, being to the extent of $\frac{1}{10}$ ths to $\frac{1}{30}$ ths of a grain per gallon.

Dr. ANGUS SMITH related several instances of serious poisonings, and even deaths, through drinking Manchester water. Though the Glasgow water was said not to be injurious to health, he believed as little as $\frac{1}{10}$ th of a grain of lead per gallon would affect many persons, whilst others might not be affected by $\frac{1}{10}$ th.

Dr. MACADAM said the water of Edinburgh was impregnated with lead only to the extent of $\frac{1}{10}$ th of a grain per gallon.

Dr. WALLACE said that he believed the cause of the action of the water upon the lead was oxygen and nitric acid. Lime also exercised a powerful action in permitting the action of the water upon the lead. He had heard of no poisonings in Glasgow by the water.

On the History of the Alkali Manufacture,¹ by Mr. GOSSAGE.

IT was correct, he believed, that the manufacture of soda in Great Britain, by the special decomposition of common salt, had its commencement in Lancashire; at any rate, its largest development had taken place in this country. Previously to the establishment of the French republic, in 1793, soda was obtained almost entirely from the ashes of marine plants growing at Alicante, in Spain, Sicily, Teneriffe, and on the coast of Great Britain. Large quantities of potash were also imported from Russia and America, but now soda was exported to those countries which formerly sent us potash. The importation into France of alkali being stopped by the French Revolution, a committee was appointed by the French Convention to discover means of supplying the article from France alone. The process suggested by Le Blanc was approved of, but it was erroneous to suppose that his process was not invented before the committee was appointed. Having given an account of Le Blanc's invention, Mr. Gossage said that it was very complete, and was the same as now used in both England and France. This invention had done more to promote civilisation than any other chemical manufacture. The

¹ Read before the British Association.

¹ Read before the British Association.

poor inventor, however, met with the too common reward of talent, and after great privations died in an asylum for paupers. Sundry alkali works were erected in France, but the process was not introduced into England for some years afterwards. In 1787 Messrs. Gordon, Barrow and Co., of Aberdeen, applied chlorine, then recently discovered, to the process of bleaching. A large establishment was, in the following year, established at Bolton. At first chlorine was used in the state of solution in water, but the inconvenience of using it in that manner was overcome by the addition of potash to the water. The next step was to substitute lime for potash, producing solution of chloride of lime. This was the invention of Mr. Charles Tennant, of St. Rollox, who afterwards manufactured chloride of lime in the state of powder. This manufacture was carried out to a great extent. A great obstruction to the manufacture, however, was the high excise duty on salt, which operated most injuriously. When Mr. Tennant's patent for manufacturing bleaching powder expired, other parties began the same manufacture. Attention was directed to the utilisation of the mixed sulphate of soda and sulphate of manganese resulting from this manufacture, and carbonate of soda, in crystals was gradually introduced into the market. During the same period, Mr. Losh was making crystals of soda, and might be considered the father of the soda trade in this country. Mr. Losh finished his education on the continent, where he learnt Le Blanc's processes. After his return, he obtained permission of Government to work a spring of weak brine discovered at Walker, on the Tyne, for the manufacture of soda. He there manufactured soda crystals; but notwithstanding these essays, 1833 might be considered the natal year of the soda trade as a special manufacture in Great Britain. In that year common salt being relieved from fiscal impost, Mr. James Muspratt commenced the manufacture of sulphate of soda at Liverpool, to be used for the manufacture of carbonate of soda. Mr. Muspratt adapted Le Blanc's processes in their entirety. He had to contend with many difficulties, but he overcame them all, and reaped a satisfactory reward. Other manufacturers also commenced to make sulphate of soda, by the special decomposition of common salt, for the purpose of making soda; and it had since been found advantageous to adapt this method of working to the production of bleaching powder, by using the hydrochloric acid so obtained to generate chlorine by its action on manganese. In the early days of the soda trade no attempt was made to condense and liberate hydrochloric acid gas. The old apparatus of cylinders and Wolfe's bottles were totally inadequate for the condensing. Many plans were suggested, and amongst others he (Mr. Gossage) obtained a patent in 1836. Having demonstrated the practicability of effecting a complete condensation of hydrochloric acid by the erection and working of a set of apparatus at the soda works with which he was then connected, he introduced the plan to the trade, and it had been subsequently adopted by every manufacturer. The principle of the invention consisted in causing the acid gas to percolate through a deep bed of coke, in small lumps contained in a high tower, at the same time that a supply of water flowed very slowly over the surfaces of the pieces of coke. By this means, an almost unlimited extent of moistened surfaces might be presented to the gas for effecting its absorption, and as the same fluid descended through the tower, it met with more gas and gradually became charged to saturation; whilst, at the upper portion of the tower, any gas

which might otherwise escape was exposed to the absorbing power of unacidulated water. In 1838, a French house, Messrs. Fai and Co., of Marseilles, obtained a monopoly from the King of Sicily for the export of sulphur. This caused an advance in price to 14*l.* per ton from the previous rate of 5*l.* per ton. It was soon found that in our Cornish mines and in those of Wicklow, in Ireland, we possessed an inexhaustible supply of sulphur in the form of pyrites; our practical chemists soon availed themselves of this source, for the manufacture of sulphuric acid. In working with pyrites it was found that this mineral contained sulphide of copper, as well as sulphide of iron, and, at an early period, he commenced to extract the copper from the burned residuum by smelting. At the present time, the products obtained by the soda manufacturers were soda ash, worth 3*l.* per ton; soda crystals, about 4*l.* 10*s.* per ton; bleaching powder, 9*l.* per ton; bicarbonate of soda, 10*l.* per ton; whilst the cost of raw materials, now used in Lancashire, are sulphur, 8*l.* per ton, for which was substituted pyrites at a cost equivalent to 5*l.* per ton; sulphur salt 8*s.*; zincstone, 6*s.* 8*d.*; fuel 6*s.* per ton. Thus, with a reduction in the cost of raw materials not more than equal to 10 per cent., the public was supplied with the products of the soda manufacturer at a reduction of at least 60 per cent. As nearly as he could obtain information, there were 50 establishments in Great Britain, in which soda was manufactured by Le Blanc's process, producing about 3000 tons of soda ash, 2000 tons of soda crystal, 250 tons of bicarbonate of soda, and 400 tons of bleaching powder per week. The total amount of these products might be estimated as exceeding two millions sterling, which was so much entirely added to the annual income of the country, excepting about one hundred thousand pounds paid for materials obtained from other countries. He must not omit to notice the prospect of a new market for British-made soda which had been opened by the successful labours of Mr. Cobden, in negotiating the commercial treaty with the French Government. Many attempts had been made to supersede Le Blanc's process, by some more direct means of operating on salt, so as to eliminate its soda at once. Up to the present time, the result of all these attempts had been the wasteful expenditure of large sums of money. Two-fifths of the total cost for raw materials was incurred for pyrites, from which to produce a supply of sulphur; and it was a well-known fact that more than nine-tenths of this sulphur was retained in the material called "alkali waste," which was thrown away by the manufacturer. Thus was presented a problem which, if it could be solved, would effect a large reduction in the cost of soda. Many chemists, both scientific and practical, had given a great amount of attention to that subject. He had been so unfortunate as to be amongst the number, as he had devoted a great proportion of his time, during a quarter of a century, and a large amount of both money and labour to this hitherto delusive subject. He commenced by demonstrating in 1838, that one equivalent of sulphide of calcium produced monocarbonate of lime and sulphide of hydrogen. This decomposition was contrary to the received views of scientific chemists of that day, as it was held that an excess of carbonic acid was needful to effect the perfect decomposition of sulphides. He was convinced that whenever the utilisation of the sulphur in alkali waste might be effected, it would be by means of this action of carbonic acid. He demonstrated also, at the same time, that one equivalent of carbonic acid would decompose one equivalent of sulphide of sodium, producing monocarbonate of soda

and sulphide of hydrogen. His present impression was, that Le Blanc's process would be modified by the omission of lime, when decomposing sulphate of soda, thus producing sulphide of sodium; and that the carbonic acid evolved by this decomposition would be applied to decompose the sulphide of sodium producing carbonate of soda, and eliminating sulphide of hydrogen, which would be absorbed by peroxide of iron, and the product in the manufacture of sulphuric acid. He had proved the practicability of all those decompositions and actions; but the ideas had still to be worked into a practical operation.

NOTICES OF BOOKS.

A Manual of Chemistry, Descriptive and Theoretical. Part I. By WILLIAM ODLING, M.B., F.R.S., Fellow of the Royal College of Physicians; Secretary to the Chemical Society; and Professor of Practical Chemistry at Guy's Hospital. London: Longman, Green, Longman, and Roberts. 1861.

THE first part of this important and long-expected Manual is announced for publication on October 1st. We propose, in an early number, to devote some space to a critical review of its contents, and, in the meantime, will briefly draw attention to some of the leading features in the book, in most of which it will be found to differ from other chemical manuals of similar scope:—

As a rule, the atomic weights selected for volatile elements represent single volumes, and those for volatile compounds double volumes, of their respective gases or vapours.

The great majority of compound bodies are expressed, as unitary molecules, by unitary formulæ, instead of by additive, or, as they are commonly called, rational formulæ. Throughout, the algebraic sign of addition is never used to express combination.

The equivalent notation, by means of dashes, introduced by the author some years ago, and now constantly used in the original papers of most European chemists, is here employed for the purposes of elementary teaching.

The arrangement of the book is more than ordinarily systematic. The mutual relations of the elements and of their analogous compounds are largely dwelt upon, as are also the mutual relations of the various heterologous compounds of the same element. The properties of classes of bodies, chlorides, oxides, sulphates, &c., are described with greater fulness than is customary in text-books.

The compounds of mineral and organic chemistry are not considered apart in separate sections. Moreover, the doctrines of series, types, and substitutions, are applied indiscriminately to both branches of chemical science.

The technological applications of chemistry are but very briefly referred to, and the physics of chemistry only incidentally discussed; so that a more than usual proportion of space is devoted to chemistry proper, and especially to the description of chemical reactions.

The present part contains an introductory section, and an account of the elements, hydrogen, fluorine, chlorine, bromine, iodine, oxygen, sulphur, selenium, tellurium, nitrogen, phosphorus, arsenic, antimony, and bismuth, and of their combinations with one another.

NOTICES OF PATENTS.

330. *Treatment of Soda Waste and Sulphurets.* J. L. JULLIOT, Tynemouth. Dated February 9, 1861.

By different modes of treatment the inventor proposes to economise the oxy-sulphide of calcium refuse of the alkali

manufacture, either by eliminating from it the sulphur in the free state, or by effecting its further oxidation, and so giving rise to the production of marketable compounds, having one of the alkaline earths acting the part of base.

Immense quantities of hyposulphite of soda are now being manufactured from this oxy-sulphide of calcium refuse, and in this instance the inventor appears to have in view the substitution of the cheaper bases, lime or magnesia, for the soda commonly employed. The expedient of burning out the sulphur from the waste is also contemplated in the specification.

331. *Capsules or Covers for the Necks of Bottles and Jars.* J. G. JENNINGS, Holland Street, Blackfriars. Dated February 9, 1861.

THIS invention consists in employing suitable covers, metallic or otherwise, to which a short length of vulcanised india-rubber tubing is securely attached, so as to admit of being readily turned back, and thus allow of the capsule or cover being put on to a jar or bottle with great facility, and by turning down the piece of india-rubber tubing it is made instantly to embrace that part of the jar, bottle, or aperture to which the capsule-cover has been applied. The binding or grip of the india-rubber tube will be tight or slack upon the neck of the bottle according as the interior diameter of the elastic tube is less than that part of the jar or bottle to which it is applied and may be regulated also by the thickness of the rubber employed.

The principle of this invention is highly ingenious and susceptible of very wide application. That the junction may easily in this manner be made perfectly air-tight is attested by the general practice of connecting the joints and parts of laboratory gas apparatus by short lengths of vulcanised rubber tubing. Capsule lids formed entirely of india-rubber have been found to answer well for closing the mouths of jars and wide-necked bottles. It must be borne in mind that metallic specimens and many chemical products are liable to become quickly tarnished by exposure to the sulphuretted volatile emanations which continually escape from ordinary vulcanised india-rubber; in such cases the employment of the new capsule covers would necessarily be inappropriate.

335. *The Manufacture of Sub- or Oxy-Sulphate of Lead.* A. LEIDEMANN and T. LANGR, Newcastle-upon-Tyne.

A Communication. Dated February 9, 1861. For the purposes of a white lead paint the patentees claim the production and use of white precipitates containing sulphate of lead in combination with different proportions of oxide of lead.

Provided that the pigments formed in this manner be found to possess the requisite degree of body or opacity, this treatment would very likely be found serviceable in the working up of the precipitated sulphate of lead which is obtained as a bye-product in the process of making acetate of alumina mordant from alum and sugar of lead.

337. *Artificial Leather.* E. GERVAISE and J. E. BERNIER. Dated February 11, 1861. (Not proceeded with.)

THE mode of manufacturing artificial leather is as follows:—The inventors propose to employ caoutchouc, gutta-percha, or other gums, fusible materials and substances. These are to be submitted to a sufficient degree of heat to liquify them, after which they are mixed either with cow-hair, wool, or vegetable fibres, and when desirable with waste pieces of leather or cuttings of skins. Pitch, tar, and certain oils may be substituted for the gutta-percha and india-rubber. When required to possess the greatest degree of strength the artificial leather should be subjected to the action of super-heated steam during the operation of incorporating the materials; and after perfect combination has been effected in this manner, the mass,

whilst in a warm state, is passed between pressure rollers to agglutinate the fibres and give it the required thickness, after which the material undergoes a final operation for imparting to it the appearance of natural leather. To effect this, the surface has to be coated with a varnish composed of solution of india-rubber or gutta-percha, gums, or drying oils, and is again passed between pressure rollers.

The manufacture thus described is very similar in its main features to that followed in the preparation of "American cloth," and also to that of "Clark's patent waterproof felt," which latter appears to be composed of cotton-wool matted together with gutta-percha, applied in a coal-tar naphtha medium as a paste or solution in order to facilitate the incorporation of these ingredients. The success of such a process as that defined in the specification will mainly depend upon the careful selection of the raw materials, both gums and fibres, employed in the manufacture.

358. *Manufacturing a Glutinous or Viscous Substance to be Used in Dressing Textile Fabrics, and for other such like Processes, or in Brewing and Distilling.* W. MALTBY, Camberwell, Surrey. Dated February 12, 1861.

In carrying out this invention the patentee takes ground rice and mixes it with about one-third of its weight of water, the temperature of which he prefers to be moderately warm. He now leaves it to stand for several days, with occasional stirring, until fermentation has commenced; then dries it with the assistance of artificial heat, which he regulates accordingly as the product is required to be more or less glutinous. The dry material resulting is ground to powder, and after mixing with hot water is ready for use.

The description above given, refers precisely to the ordinary method of preparing dextrin by fermentation. A process in common use consists in allowing to ferment starch, either in the form of damaged wheaten flour or ground rice, whichever may happen to be cheapest in the market at the time, simply mixed with water, and then left until fit for use, without resorting to any intermediate drying process.

365. *Refining Malt Liquors.* C. S. ROSKILLY, Falmouth. Dated February 13, 1861.

The patentee employs a mixture of malt, hops, the leaves of ground ivy, and nettles, boiled in water, and when cold he adds a small quantity of the decoction to the liquor to be refined.

The mucilaginous constituents of the two plants last named, would probably operate like gelatine in causing the more rapid precipitation or subsidence of the suspended impurities always present in malt liquors before refining.

CORRESPONDENCE.

Phosphate of Sesquioxide of Iron.

To the Editor of the CHEMICAL NEWS.

SIR,—Since attention is directed in your columns of September 21, to the manufacture of phosphate of iron, and of the probable use to medicine which will follow its production, I thought it would be well to inform your readers that the phosphate of sesquioxide of iron was made for use in medicine by my friend Mr. John Lightfoot, chemist, of Broad Oak Print Works, Accrington, more than two years ago, and that its use was attended with success. Soon afterwards the above-named gentle

man made a phosphate corresponding to the magnetic oxide, which is very freely soluble in citric acid and the neutral citrate of ammonia. This phosphate of protosequeioxide of iron has been used ever since by a surgeon in that town with marked success, in cases of albuminous and saccharine urine, and some forms of heart disease, and I have been told that Dr. Simpson, of Edinburgh, and several other medical gentlemen are in the habit of prescribing it.—I am, &c. W. R. BOOTH.

Chemical Notices from Foreign Sources.

TECHNICAL CHEMISTRY.

Processes for the Consecutive Preparation of Saltpetre, Potassio-tartrate of Soda, a pure Bitartrate of Potash, Tartaric Acid, and the Sulphates of Soda and Potash.—Guido Schnitzer gives (*Gewerbeblatt aus Württemberg*, 1861, No. 15) the following as an easy and convenient way of obtaining the above salts. He starts with equivalent weights of Chili saltpetre (nitrate of soda) and rough pot ashes which he heats, with just enough water to dissolve them, in an iron vessel, stirring well all the time. When the mutual decomposition which ensues is complete, he adds to the boiling liquid sufficient milk of lime to convert the carbonate into caustic soda. The solution containing the nitrate of potash and soda is then evaporated for the nitrate of potash to crystallise out, which the author says it does completely. The crystals are then drained from the soda solution, and washed with water slightly acidulated with hydrochloric acid, to remove the last traces of soda.

The soda solution is then used for the preparation of the double tartrate of potash and soda. For this purpose it is boiled with sufficient rough tartar to make a neutral solution. This operation is best conducted in a copper vessel. A deposit of some tartrate of lime from the rough tartar remains, which may be carefully washed and used in the subsequent process for making tartaric acid. When filtered from this deposit, the solution is evaporated for crystals of the potassio-tartrate.

When the author wishes to prepare pure bitartrate of potash, he takes the filtered solution of the double tartrate as above, and adds sufficient hydrochloric acid to combine with the soda, whereupon the bitartrate of potash separates in small granular crystals, which are drained and washed with cold water to remove any chloride of sodium.

To make pure tartaric acid, the author takes the solution of the double tartrate as before, and boils it with gypsum free from iron, whereby tartrate of lime and the sulphates of potash and soda are formed. The tartrate of lime is decomposed by sulphuric acid in the usual manner, and then (any iron having been removed by the alkali) the tartaric acid is obtained quite pure in the first crystallization. The sulphates of soda and potash are afterwards separated by crystallization.

Preparation for Gilding Porcelain.—This preparation, the invention of the Brothers Duterte, is reported on by Salvétat (*Bulletin de la Société d'Encouragement*, &c. March, 1861, p. 129). The peculiar advantage of it is, that after burning, the gold is so bright as not to require polishing. Thirty-two grammes of gold are gently warmed with 128 grammes of nitric acid, and the same weight of hydrochloric acid. To the solution are added 1.2 grammes of tin and 1.2 grammes of butter of antimony, and when all are dissolved, the solution is diluted with 500 grammes of water.

A mixture is now prepared by heating together 80 grammes of oil of turpentine, 16 grammes of sulphur, and 16 grammes of Venice turpentine. When the sulphur is dissolved, 50 grammes of oil of lavender is added. The gold solution is now added, and the two are well stirred together until the aqueous solution becomes decolorised,

showing that all the gold has united with the balsam. The watery portion is then poured away, and the oily fluid is washed with warm water, and then heated. When the last trace of moisture has disappeared, 65 grammes more lavender oil, and 100 grammes of oil of turpentine, are added, and the whole warmed to ensure the perfect admixture. While quite fluid, 5 grammes of subnitrate of bismuth are added. Afterwards, the clear part is decanted from any reduced gold and other insoluble matters, and the balsam is concentrated to a fit consistence for painting with. The balsam so prepared is a thick fluid of a pale green colour, the gold being perfectly dissolved; when proper care is taken to remove all moisture this preparation never blisters in burning.

MISCELLANEOUS.

The Polytechnic Institution.—We have already announced that Mr. Pepper has returned to the Direction of the Polytechnic Institution under the most favourable auspices. In his inaugural address he was greeted with a hearty welcome; he stated that although three years had intervened since he last appeared on that platform, the warmth of his welcome made him feel that the separation which had taken place between him and the Polytechnic audience was but then of yesterday. It made him feel that he was among friends, and he would appeal to them to aid him in the arduous duties he had undertaken. He said arduous duties, because when amusement, in its most attractive form, but totally devoid of rational instruction, was offered in other places to the public, it required no small degree of energy to manage an educational establishment in such a manner as to counteract the evil influences of the establishments to which he alluded. He would especially appeal to them to aid him, as they had aided his predecessor, Mr. Phené, by sending works of art and art manufacture to the institution for exhibition, and so increase its attractions. It would no doubt be interesting to the public to know that the Rev. J. B. Owen was chairman of the board of direction, and that the Rev. Chas. Mackenzie had taken charge of the educational classes. We understand that it is the intention of the directors of the Institution to issue honorary admission tickets, transferable, to all the eminent scientific men of the day.

ANSWERS TO CORRESPONDENTS.

* * All Editorial Communications are to be addressed to the EDITOR; and Advertisements and Business Communications to the PUBLISHER at the Office, 1, Wine Office Court, Fleet Street, London, E.C.

* * In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

The Water Supply of London.—Mr. John Frederic Bateman writes to correct the announcement made by Mr. Fairbairn in his address to the British Association respecting a scheme for supplying the metropolis with water from Wales, in which he is represented as having estimated the cost of bringing water to London from the Bagshot Sands at £12,000,000. This is altogether a mistake, arising mainly from a typographical error in a return to an order of the House of Lords in 1852. The scheme which Mr. Bateman laid before Lord Shaftesbury in that year, and which was included in the return referred to, was one for bringing the soft waters—not of the Bagshot Sands—but of the Green Sands in the neighbourhood of Hindhead and the Leith Hills, and this estimate was £1,200,000, not £12,000,000, as erroneously printed in the Parliamentary return. In a subsequent part of the same return, p. 36, the estimate is correctly given.

W. P. W.—We are not aware that any special experiments have been made with the object of producing alums, in which sulphates of any of the organic alkaloids are caused to replace sulphate of alumina.

Omega.—A full account of the spectroscopy will be found in No. 149 of the *Photographic News*, for July 12, 1861, or it will be forwarded on application to Spencer, Browning, and Co., 111, Minories.

Curmione of Indigo.—A correspondent wishes to know the best way of preparing the above.

THE CHEMICAL NEWS.

VOL. IV. No. 96.—October 5, 1861.

THE PRESERVATION OF BUILDING STONE.

THE following Report has been addressed to the Right Hon. William Cowper, M.P., Chief Commissioner of Works, &c. We propose next week to give an analysis of the different projects for the preservation of stone which have been brought before the notice of the Committee.

We, the undersigned, being the Committee appointed "to inquire into the decay of the stone of the New Palace of Westminster, and into the best means of preserving the stone from further injury," have the honour to submit to you the following Report, in which we have adopted as the objects of our inquiry the several points referred to us by your letter of appointment and instruction, viz. :—

"I. The extent and position of the decay.

"II. The causes to which it is attributable, taking into consideration the composition of the stone, and the influence exerted upon it by moisture, and by the acids diffused in the London atmosphere.

"III. The best means of preserving the stone from further injury.

"IV. The qualities of the stones to be recommended for future use in public buildings to be erected in London."

1. In proceeding with the important inquiry thus intrusted to this Committee, we beg to state, that we first made a careful inspection of the whole of the buildings; and that after this inspection we proceeded to obtain such evidence as appeared to us best calculated to facilitate the inquiry intrusted to us, by examining a considerable number of witnesses who had been connected with the building from the commencement, or who had been concerned in the various processes which had been actually tried for arresting the decay which had occurred; and also another class of witnesses, who had suggested various theoretical remedies for the same purpose.

2. We delegated to a Sub-Committee, specially appointed, an examination and inquiry into the condition of other buildings erected in the metropolis, in which magnesian limestone had been used, and we particularly called the attention of the scientific chemists who had been appointed on the Committee to several points peculiarly within the limits of their acquaintance with chemical subjects.

3. We also considered it expedient to invite by advertisement the attention of chemists and others to the subject submitted to the Committee, requesting that any plan or suggestion for the prevention of decay, or for arresting its progress, might be brought under our notice.

4. Having thus premised the course the Committee thought it expedient and desirable to take, we now proceed to report *seriatim* on the subjects brought under our notice by your instructions, and in the order adopted therein.

I. *The Extent and Position of the Decay.*

5. It is extremely difficult to give any very exact account either of the extent or actual position of the decay. It seems from the evidence that it first began to make its appearance in the portions of the Palace at Westminster executed at the commencement of the building, about seven years after their execution; and yet, in some of the most recently executed portions, viz., those towards Old Palace Yard, facing Henry the Seventh's Chapel, the decay appears to be as obvious as in any other part of the building.

6. In the earlier works, viz., those towards the Thames, the decay is most apparent in the lower portion of the building, and in this portion the decay is confined to what may be called "zones," or general levels, which would seem to suggest that it depends as much upon position in the building as upon the use of particular beds of stone from the quarries employed.

7. The same remark applies to the part of the Palace fronting the approaches to Westminster Bridge, where the decay of the lower portion is considerable; but in the newest work, facing Henry the Seventh's Chapel, the decay occurs in positions which are more varied, and under circumstances which it is exceedingly difficult to appreciate.

8. We have examined with much care the upper portions of the building, and we cannot perceive that the decay has made any important inroad upon those much more exposed portions, where decay might more reasonably have been expected. The decay, however, occurs again to a considerable extent in the inner courts, which are sheltered in a great measure from external influences; and perhaps the very worst specimen we have noticed is to be found in the small archway leading to the reporter's gallery, near the entrance to Westminster Hall—a part of the work as much sheltered as in the nature and circumstances of a public building it could well be.

9. The general result of our observations, confirmed by the evidence, would seem to suggest that the stone used in the Palace of Westminster is much more likely to decay in damp and sheltered situations than where it is exposed to the full action of atmospheric influences. In the east and north fronts, before adverted to, the worst symptoms occur in the ashlar between the upper and lower mouldings of the plinth, and under the first cornice, where the exposure is inconsiderable; but the dampness, arising from the drip of the mouldings and from the action of capillary attraction, in cases where projections hold the moisture, appears to exercise an important influence on the condition of the stone itself.

10. It does not appear to us that the decay is attributable, as is commonly supposed, to the stones in the building not being placed upon what is technically called their natural bed, or in the same relative position as they occupied in the quarry; thus, stones which are found horizontally in the quarry, appear to have been often

placed perpendicularly in the building, and used for purposes of the most delicate decoration without any injurious result. As an instance of this fact, we may point out the elaborately carved shields of arms under the range of the first-floor windows; the stones used for those shields, though universally placed perpendicularly to their natural position in the quarry, present, so far as we are aware, few, if any, symptoms of decay.

11. The extent to which the decay on the whole surface has proceeded, it is not very easy to estimate. At the present moment the actual decay is doubtless considerable for a building so recently erected; but the change of colour in the stone itself, and the "fretting out of the surface," which are suggested as the first symptoms, lead us to apprehend that there may exist much more mischief than at present is actually apparent.

12. One of the witnesses examined, however, and whose judgment as a practical man is of considerable value, is of opinion that the decay, after proceeding to some depth in the stone, stops of itself; that an induration of the surface takes place, and that no further decay ensues. The Committee would willingly accept this opinion if they considered it well founded, but they cannot conceive that it is true to any considerable extent, notwithstanding there may certainly be some few indications which lead to the belief that in some cases it may be correct.

13. At present the decay appears for the most part on the plain surfaces, whilst the finer and more elaborately wrought portions of the building, unless under projections, are not seriously affected. And however disappointing and disfiguring these defects may be, especially in a building so recently erected, the Committee are of opinion that at present the decay does not affect the stability of the structure.

II. The Causes to which the Decay is attributable.

14. This part of the inquiry naturally leads to a reference to the evidence which has been obtained by the Committee on the subject of the stone itself. The result of this evidence may be thus briefly stated. The stone recommended by the Commissioners for this building was that from the quarries of Bolsover Moor and its neighbourhood, and this stone was actually contracted for in the first instance. Before the work began, however, it was found that blocks of sufficient size could not be procured from those quarries, and, in consequence, one of the Commissioners was appointed to proceed to the spot, to ascertain whether other quarries might not be discovered furnishing stone in beds of greater thickness and of larger dimensions. These conditions were found in the quarries of Anston, and the stone of greater thickness produced from these quarries has been used not only in this building, but in all the other buildings constructed of magnesian limestone in the Metropolis, after the quarries of Bolsover Moor had been abandoned, for the reason above stated.

15. The recommendation of the Bolsover stone in the Report of the Commissioners was founded on its similarity to that used in the Norman portions of Southwell Minster, which were stated in the Report to be in a high state of preservation. Evidence has since been adduced, in a letter from Mr. Scott, to be found in the Appendix, which renders it probable that the stone of this Minster was really obtained from the ancient quarries at Mansfield Woodhouse. The latter quarries were re-opened, and a considerable quantity of stone from them (exceeding 20,000 cubic feet) was made use of in the Palace at

Westminster; but in their turn they were relinquished from dissatisfaction as to the size of the blocks, though we have it on evidence, confirmed by our own observation, that the stone used from these quarries has stood remarkably well.

16. The evidence brought before your Committee on the subject of the stone obtained from the Anston quarries is very conflicting; the contractor and his principal foreman stating that the stone was, with slight exceptions, extraordinarily good, while other witnesses maintain that, even in the quarries themselves, there are stones in a state of actual decomposition; and one very important witness, a foreman employed at the Palace at Westminster, asserts that he knew that certain beds in some of the quarries were liable to decay, and that he abandoned them in consequence. With reference to the selection of stone, the Committee venture to remark, that it is much to be regretted that the offer made by one of the Commissioners particularly well acquainted with the selection and working of stone, to examine that used in the Palace at Westminster for the moderate salary of 150*l.* per annum was not accepted, owing to some difficulty in regard to the party who was to be held responsible for this unimportant amount; and that the matter was left to persons who admit that they had little or no prior experience of this description of stone, though they evidently entertained suspicions of the durability of some of it which they were employing.

17. With reference to the very natural and important question of the actual causes of the decay of this stone when exposed to the London atmosphere, the Committee take the liberty of referring to the Report of the chemists who were members of the Committee to whom this question was specially referred. This will be found in the Appendix.

III. The best Means of Preserving the Stone from further Injury.

18. This part of the inquiry referred to the Committee naturally divides itself into two questions: namely, as to the steps that have hitherto been taken, whether experimentally or otherwise; and as to those that are to be recommended for adoption hereafter. With regard to the first question, we have ourselves examined with care the result of what has been done at the Palace itself, either experimentally on the river front, or, as in the inner courts, by actual coatings or washings over large surfaces. With regard to the second question, our inquiries have been earnest and elaborate, and we have examined many witnesses and given much time to the consideration of the various propositions obtained by advertisement or otherwise. As will be seen in a subsequent part of the Report, we finally referred this question to the further consideration of the professional chemists who were on the Committee.

19. On the first question, the Committee are decidedly of opinion that it is not necessary nor desirable to proceed with any general coating, painting, oiling, or washing of the whole building. It is quite obvious, in their judgment, that a very large proportion of the stone does not require any such application; but that what is wanted is some efficient process which should be applied to the surface of any stone that begins to show symptoms of decay, with a view to arrest its progress. The Committee believe that the persons to whom the care of the building is entrusted ought to watch it, and note in the very earliest stages wherever decay is perceptible, by efflorescence, change of colour, crumbling, or slight decomposition.

20. In cases where the decay is important, and evidently occasioned by the fall of rain on an upper projecting or exposed surface, protection should be afforded by a covering of sheet zinc or lead; and if hereafter any composition should fortunately be discovered, by which the decaying stone could be at once covered or coated, and the injurious influences of the atmosphere prevented from further acting upon it, the difficulty would be solved. In some extreme cases the decayed stone might be cut out, and replaced by a new one. With regard to the processes which have actually been applied, whether experimentally or extensively, your Committee are decidedly of opinion that the discovery of a proper mode of treating stones in a state of decay has not yet been made, and there is no evidence whatever on the building itself to induce them to believe that the decay, where decay has arisen, has been arrested, or that permanently the decay has been prevented by any of the processes yet applied.

21. With reference to the second question, we found ourselves unable, after much labour, to come to any definite conclusion; and we finally requested the chemists in the Committee to examine and report upon it; but those gentlemen state, as appears by their Report in the Appendix, that the nature of the inquiry is so extensive, and that time is so important an element in the solution, that they are unable to give any opinion upon the subject. They further state, that they spent five whole days in the examination of only one suggested remedy, but they are unable, notwithstanding, to give any opinion on even that one suggestion. They allude to secret processes, regarding which they say they can offer no opinion, but they express a doubt of the applicability of any suggestion which would demand the veil of secrecy for protection. Concurring in this view, it may be further noted that even if such applications were found successful in sample or experiment, no security would be afforded for a corresponding success in any subsequent large operations. They recommend that a series of experiments should be conducted under chemical supervision for a considerable period of time, and the Committee are most reluctantly compelled to coincide with them, and to urge upon the Government the adoption of such a course.

IV. The Qualities of the Stones to be recommended for future Use in Public Buildings to be erected in London.

22. On this head of the inquiry the Committee have been unable, in the time allotted to them, to go into any very extensive examination. It is obvious, however, that although some varieties of magnesian limestone are an excellent and durable material, when not exposed to the deleterious influences of the London atmosphere, yet that in London it is subject to causes of decay, which render it an undesirable and unsafe material for the construction of public buildings.

23. It is equally obvious that Portland-stone, well selected, has been used in buildings in London from the date of St. Paul's downwards, under circumstances of great exposure, and with most successful results. Portland stone is a material to be obtained in any quantity, and in blocks of any size, beautiful in colour and texture, reasonable in price, not by any means so hard as the Anston stone, and yet with a power of resisting the influences of the London atmosphere, that leaves but little to be desired. It must be remarked, however, that Portland stone should be carefully selected, an operation which would be the most satisfactorily effected by an agent at the quarries.

24. On this subject the Commissioners could of course bring much personal experience to bear; but after the valuable explanation of the principles upon which the decay of stone depends in populous places as given by the Chemists, in their Report before referred to, the Committee refrain from repeating those conclusions, in which, however, they entirely concur.

25. During the inquiries of the Committee, one of their members, Mr. Burnell, who is well acquainted with architectural and engineering works in France, undertook, at his own expense, a journey to Paris, to inquire into the practice of the French architects engaged in the Government works in that metropolis. There, the stone used, the "calcaire grossier," though a carbonate of lime of tertiary age, and, therefore, of very different mineral composition from our magnesian limestone of the much older Permian age, seems to suffer also from decay in a comparatively pure atmosphere, and where wood is chiefly used as fuel.

26. From the evidence of Mr. Burnell, it does not appear that French architects or chemists have been more successful than ourselves either in the use of materials not subject to atmospheric influences, or in the application of processes for arresting decay, when it has once begun. The opinions of the most scientific chemists and architects in France on this subject have, however, in this way been obtained, and it is extremely probable that the inquiries undertaken by them, simultaneously with those undertaken in this country, may hereafter lead to some successful result.

27. The Committee have to thank the Government for the facilities given to Mr. Burnell in this important part of the inquiry, by providing him with an introduction which obtained for him the active assistance of Her Majesty's Ambassador at the Court of the Tuilleries.

28. The Committee delegated, as before stated, to a Sub-Committee the duty of examining the various buildings in London in which magnesian limestone from the Anston quarries has been introduced in the external architecture. The Report of this Sub-Committee forms part of the Appendix; and we beg to refer to that Report as confirmatory of our opinion of the uncertain character of magnesian limestone, and the risk attending the use of it in London.

29. In conclusion, the Committee venture to recommend that the architect of the Palace at Westminster, assisted by scientific chemists, should examine and record the actual state of the stone work of the building at the present moment; that experiments should be made by their direction, under various conditions of height, exposure, and aspect, with such preservative materials and agents as the chemists may suggest from time to time, and that researches should be continued into the effects of the various alkaline silicates, the phosphates, and other substances which have been brought under the notice of the Committee, or suggested in Germany, France, or elsewhere; that where decay arises from damp, means should be taken to protect the stone, as has been before suggested; that any stone extensively decayed should be removed and replaced; but that in particular the earliest symptoms of decay should be carefully watched, and examined with the view to the application of some immediate remedy. The Committee believe that a very large portion of the stone in the Palace at Westminster is of a very durable nature, and they entertain a confident expectation that a remedy will soon be found to arrest or control the decay when it has unfortunately begun to appear.

 CHARLES H. SMITH, EDWARD M. BARRY.
 ALFRED BONHAM-CARTER, Secretary.

The following letters have been addressed to the Chairman of the Committee on the Decay of Stone of the New Houses of Parliament:—

June 17, 1861.

Sir,—We have the honour to inform you that we have complied with the wishes of the Committee by examining into the several proposals which have been laid before them for the preservation of the stone of the New Houses of Parliament; and that we have arrived at the following conclusions:—

1. Amongst the processes proposed, varying in principle and value to a very considerable extent, there is not one which we at present feel justified in proposing that the Committee should definitely recommend as a preservative, either for general or local application.

2. A minute examination into one class of processes, submitted to the Committee at an early period, has convinced us that, surrounded with great difficulties as the subject appeared at the outset, the obstacles eventually met with in an effective experimental inquiry are of a far more formidable character than could have been anticipated. Having devoted five days exclusively to the practical study of one of those processes (Ransome's), and having been unable, in that period, to elaborate even this single process sufficiently to warrant us in expressing a definite opinion upon its merits, it is obvious that anything like an elaborate examination of the numerous proposals which have only just now been submitted to us, would require the expenditure of a far greater amount of time than the Committee could place at our disposal.

3. Whilst regretting that it is not in our power to lay before the Committee a positive recommendation of any particular process, we beg to submit the following observations:—

An examination into the nature of the several processes proposed leads to their classification, under two heads:—

(a) Processes which are likely to afford permanent protection to the stone.

(b) Processes which are only calculated to afford protection of a temporary character.

In both of these classes there are proposals which may at once be excluded from further consideration, on account either of their inapplicability to stones when placed in a building, or of the obvious misapprehension, on the part of the proposers, of the problem to be solved.

A proposal to protect stones by immersion in a boiling mixture of pitch or resin and oil, may be quoted in illustration of the processes which are only applicable to stones previous to their having become integral parts of any structure; again, the suggestion to cover the building with a coating of a mixture of silica with sulphur, applied in a semi-fluid condition, would involve almost insurmountable difficulties in its practical application, not to speak of the inflammability of the sulphur, which is only slightly diminished by the presence of the silica, or the uncertainty of the temporary character of the protection which, even under the most favourable circumstances, could be afforded by this material.

Several of the suggestions are based upon notions so obviously erroneous, such as coating the building with sulphate of lead, and procuring an alleged galvanic protection, by establishing connections of this coating with plates of zinc; or, of ridding the building of the principle of decay by fermentation, that no object whatever could be gained by entering more fully into the merits of these proposals.

Of the processes which are intended to afford permanent protection to the stone, and the use of which is not precluded by the conditions of the case, there are several which claim a careful investigation. These processes may be classed under the following heads:—

1. Application of silicates of the alkalies, in various states of concentration.

2. Application of silicates, in conjunction with various saline compounds, intended to produce double decomposition.

3. Application of hydrofluoric, or hydrofluo-silicic acid, or their saline compounds.

4. Application of phosphoric acid, and acid phosphate.

5. Application of solutions of the alkaline earths, or their bicarbonates, in water.

All these processes are more or less based upon chemical considerations, which are supported by analogy, and which, in the case of the two first-named classes, have received considerable experimental confirmation. The experiments which are now in progress with several of the processes included in the two first subdivisions will, we believe, in the course of a few years, furnish ample data for correct conclusions regarding their applicability. In the meantime it might be advisable to apply to portions of the New Houses of Parliament actually undergoing decay, certain processes selected as representatives of the remaining classes above enumerated, in order that their merits might be submitted to the only conclusive tests, those of actual application, and protracted exposure to the corrosive influence of a London atmosphere.

The second division of processes,—namely, those which are only calculated to afford protection of a temporary character, are, from their very nature, of minor importance for the purposes of the Committee's inquiry; nevertheless, as the claims to permanence of none of the processes of the first division have as yet been substantiated by the test of time, we would recommend that, in addition to the experiments already made in this direction, further trials be instituted of some of the more promising materials of this particular description. This recommendation is based upon the consideration that substances, included under the appellation of organic, differ essentially in their powers of resisting the destructive action of the atmosphere. Whoever is acquainted with the nature of organic substances, cannot fail to appreciate the different degrees of stability under atmospheric influence exhibited by gluten, gelatin, or starch (which we find enumerated among the proposed protective agents), and by bees-wax and paraffin, not to speak of many of the fossil gums, which exhibit a degree of permanence approaching that of mineral substances.

The materials which we would recommend for selection to be tried in comparison with linseed oil, are paraffin, bees-wax, and some of the more permanent gums and resins, applied in the form of solutions in volatile solvents.

We should not omit to remark, that some of the witnesses and others who have addressed the Committee, speak of secret processes. We cannot of course offer

any opinion regarding such proposals, but we should doubt the applicability of any suggestion which would demand the veil of secrecy for protection.

Finally, we beg to state, as the result of the experience which we have been enabled to acquire during the prosecution of our investigations on this subject, that a definite solution of the question at issue can only be arrived at after the lapse of a considerable period, since the relative merits of the processes which we recommend for trial can be established only by the test of time.

We have, &c.,

(Signed)

A. W. HOFMANN.

E. FRANKLAND.

F. A. ABEL.

(To be continued.)

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Researches on the Relations existing between Atomic Weights, by M. J. S. STAS, Member of the Royal Academy of Belgium.

ALL the analytical researches undertaken for nearly a century past tend to show that compound bodies possess a definite, constant, and unvariable composition. The proportions deduced from these researches have been successively termed "Proportional numbers, chemical proportions, chemical equivalents, or atomic weights." The illustrious Berzelius devoted a great part of his life to settle the relative weights of these chemical proportions. His works on this subject remain imperishable monuments of his penetration and genius. The minute and reiterated control to which I have had the presumption, not to say the temerity, to submit them has convinced me that his analytical skill has never been surpassed—in fact, has never yet been equalled. Berzelius, it is known, concluded from his researches that no relation whatever existed between the atomic weight of bodies. He remained convinced of this fact all his life.

In 1815 Dr. William Prout, in a memoir entitled "The Relation between the Specific Gravity of Bodies in their Gaseous State, and the Weight of their Atoms," propounded the idea that the atomic weights of those bodies best ascertained at that time might be represented by multiples of the atomic weight of hydrogen. Prout had sufficient diffidence as to the correctness of his hypothesis to publish his work anonymously. Whatever may be the general opinion of this hypothesis, or whatever fate is reserved for it, it is impossible not to pay homage to the rare penetration of its author. True or false, matters not; it enabled him to divine the specific gravity of hydrogen forty years before it was determined in an almost absolute manner by experiment.

In a philosophical point of view the compass of Prout's idea is immense. In England this hypothesis has been very generally accepted as an absolute fact. The work published by Professor Thomas Thompson, of Glasgow, to support it by analytical experiment, contributed much to this result. Yet it was not so in Germany and France. The immense *prestige* which surrounded the name of Berzelius, and the great confidence which his works upon atomic weights inspired, was undoubtedly the reason. Doubts even arose in England in 1833. Professor Turner, at the invitation of the British Association for the Advancement of Science, undertook a series of analyses, from which he came to the conclusion that the hypothesis of Dr. Prout was not correct. In 1839 Pro-

fessor Penny, of Glasgow, arrived at the same conclusion, although his results differed in various points from these obtained by Turner. The determination that M. Dumas and the author made in 1839 and 1840 of the atomic weight of carbon again drew the attention of chemists to this subject. The carbon atom derived from the synthesis of carbonic acid, agrees entirely with the fundamental hypothesis of Prout. The new synthesis of water that M. Dumas made known in 1843, and which was confirmed by the works of MM. Erdmann, and Marchand, lead to the same result. In 1842 and in 1843 M. de Marignac, of Geneva, undertook a series of experiments upon the atomic weights of chlorine, bromine, iodine, nitrogen, silver, and potassium, with the view of submitting Prout's law to a new and rigid examination. The Genoese chemist, whose accuracy is well known, and to whose ability and conscientiousness Berzelius paid the homage which they deserved, stated most positively that the unity taken by Prout was too great by one-half, as far as chlorine is concerned. But he stoutly declared, that, considering the extreme difficulty of arriving by experiment at absolutely accurate results, the atomic weights that he had found for silver, potassium, bromine, iodine, and nitrogen, should not be considered as contrary to Prout's law. Thus, according to M. de Marignac, the principle may be correct, only the unity ought to be lessened by one-half.

Towards the end of 1857 M. Dumas published a memoir "On the Equivalents of Simple Bodies." As might have been expected, this work produced a great sensation. The celebrated French chemist, relying upon the works of M. de Marignac on silver, found that all the well-known bodies which he had had occasion to examine obeyed perfectly Prout's law, provided this law were slightly modified. According to him, the simple bodies are multiples of hydrogen either by 1, or by 0.5, or by 0.25. My illustrious master accompanied his work by important considerations on natural philosophy, but which have no connexion with the question of which I intend to treat.

Such is the present state of our knowledge of the relations between the atomic weights of simple bodies.

For several years I have devoted all my leisure to elucidate this problem. I will say candidly, that when I undertook my researches I had an almost implicit confidence in Prout's law. The doubt that I expressed in my work on the atomic weight of carbon, published in 1845, being owing to the result of two determinations which would not agree with my other synthetical experiments. My investigations have been on chlorine, bromine, iodine, fluorine, sulphur, nitrogen, potassium, sodium, lithium, calcium, barium, lead, and silver. It will scarcely be credited that during the long and tedious work to which I had devoted myself, I obtained successively the most discordant results, according to the body and the means I employed. Sometimes these results agreed entirely with Prout's law, as, for example, in the case of lead, silver, sodium, and calcium defined in relation to the atomic weight of carbon; at other times they were thoroughly at variance with this law, as in the case of lead determined in relation to the atomic weight of nitrogen and sulphur; of silver determined in relation to nitrogen and chlorine; of potassium in relation to oxygen and chlorine.

I am able to state without fear of being contradicted, that every chemist who has devoted himself to researches on the atomic weights, if he has varied his methods of operating, if he has sought for the atomic weight of a body by referring it to the atomic weights of two or

three different bodies, has met the same obstacles and the same contradictions. The most tedious perplexities have in this way attended my investigations.

Although I have but lately made it known to the Academy, begging them to take note of my assertion, all doubt has since disappeared from my mind. I have acquired the most complete conviction, and the greatest certainty that man can feel on such a subject, that Prout's law, with all M. Dumas' modifications, is a mere illusion, an hypothesis absolutely contradicted by experiment. Chemists, after having examined the work which I have now the honour of presenting to the rigid scrutiny of the Academy, if they can divest themselves of their prejudices and their present ideas on the subject, and keep to experiment, will soon arrive at my conviction, which is—That no common divisor exists between the weight of the simple bodies which unite to form all definite combinations.

The present work only contains my researches on nitrogen, chlorine, sulphur, potassium, sodium, lead, and silver. I have chosen these bodies because they are well known; they give the most stable compounds, and are supposed generally to obey Prout's law.

I have sufficiently explained that the object of my work is not to determine the absolute atomic weight of these bodies, but only the relation between their atomic weights, so as to see if there exist among these relations a common divisor. I have employed methods which, to my mind, are likely to give the most certain results; and in varying the processes I have given the preference as much as possible to those which have been already used by chemists of well-known accuracy. In this way I have obtained the most valid results.

It is clear that if these results, repeated several times, agree with those previously obtained, the probability is in favour of their accuracy; if, on the contrary, they differed, I found, by studying attentively all the conditions of the experiment, the way to ascertain the truth. I have thus discovered errors which would otherwise undoubtedly have escaped me.

Although the end I had in view was to search for the relations between certain numbers, I have nevertheless made two determinations, both of which assist to deduce from all my experiments the atomic weight of the seven simple bodies in relation to oxygen. We shall soon see that the atomic weights are very similar to those generally accepted, with the exception of nitrogen.

The determinations of these relations have been made either by synthesis or by double decomposition. I have only had recourse to analysis to obtain the means of calculating the atomic weights in relation to oxygen.

Before giving a succinct account of my researches, I ought to explain for the extremely large quantity of material with which I have experimented. These quantities may well astonish chemists. I did not, however, break through the established rules without due consideration. I can quote two precedents in the history of science:—M. Dumas, in his memoir on the composition of water, and M. de Marignac, in his work on the atomic weights of chlorine, nitrogen, and silver, previously employed large quantities of material. For myself, in my memoir on the atomic weight of carbon, published in 1845, I have increased tenfold the weight of the quantities usually employed. Up to the present time, as far as I know, no one has objected to this method of operating.

If we examine attentively the atomic weights which are generally recognised, and compare them with what they should be according to Prout's law, we shall soon

see that they are separated by unimportant variations. Besides, if it were not so, the problem would have long been solved. But experiment shows that the only means of proving with certainty, and of measuring exactly, the small discrepancies, is by increasing the quantities which produce them, so as to make a great disparity between these errors and those of the experimenter, which must be deducted from them. It may be imagined that the difficulties of the researches increase with the increase of quantities. Those chemists who may take the trouble to verify my results in all the various stages, will soon perceive that this is not the case: the only real inconvenience resulting from the use of large quantities is the length of the experiment, which in some cases is increased in the same ratio as the quantity. But, in return, if they continue the experiment to the end, the result carries conviction with it, because it is susceptible of only one interpretation; whilst, by employing less quantities, one is always apt to regard slight variations in the experiments as due to the inevitable errors of manipulation. One remains in uncertainty; and besides that, truth sought is liable to be lost altogether.

In looking over works treating of the atomic weights, I have often regretted that all the details of the experiments are not stated. I have thus been deprived of the means of satisfying myself as to how far the results merited the confidence which has been given to them. Being desirous, therefore, in all that concerns the results of my own researches, to give to every one the means of verifying and correcting them if they desire to do so, I have, therefore, endeavoured to give in the present memoir a minute description of every condition through which my determinations have passed. For this reason I have described accurately the balance and weights which I used to weigh them, the methods employed to guarantee the exactitude of the weights, the materials and the vessels; and to preserve the identity of the weight of the vessels during and after the experiment, I have also mentioned the nature of the vessel in which each operation was made.

I commence by showing how I prepared the substances submitted to experiment, the substances I made to react upon them, and lastly, the means employed to find the purity of each.

It is impossible to reproduce in this work a complete detail of my experiments; I shall therefore confine myself to the facts indispensable in appreciating the value of my researches, and the confidence which they should inspire.

(To be continued.)

On Tinkalite (Borate of Lime and Soda) from Peru,
by T. L. PHIPSON, *Phil. Nat. Doct. Bruxelles University, Member of the Chemical Society of Paris,*
&c. &c.

THE useful mineral of which I am about to speak was discovered only a few years ago in the deposits of nitrate of soda in Peru. It is now imported into Europe in considerable quantities as a substitute for borax. It was first examined in 1850 by M. Ulex, who found that it contained boracic acid, lime, and soda; but the analysis published by this author shows too small a quantity of water and too much boracic acid. In 1859, M. Kletzinaky received some samples of this same mineral from the Western Coast of Africa, and the analysis he has made

of them coincides pretty well with my analysis of some specimens from Peru.

Tinkalzit is found in the layers of nitrate of soda of Southern Peru, in the shape of irregular globular masses, which the natives call "tiza," and which vary in size from that of a nut to that of a potato. The outer crust of these tubercles is rather hard, but they are easily broken, and are then seen to be formed, in the interior, of a mass of crystalline needles intersecting each other in all directions, and of a brilliant white, satiny appearance. Often these globular masses contain reddish crystals of gypsum and other minerals; and they always contain a certain quantity of common salt, which gives to the mineral a brackish taste.

Water extracts from tinkalzit all its chloride of sodium and borax; acids easily dissolve the whole mineral, leaving only a small residue of very fine sand.

The density of tinkalzit I find to be 1.93 (according to M. Kletzinsky, = 1.9212; and according to M. Ulex the satin-like fibres, = 1.8). The analysis of the mineral in question has given me the following result, by the side of which I have placed the analysis of M. Kletzinsky:

	American Tinkalzit. Phipson.	African Tinkalzit. Kletzinsky.
Water	34.00	37.40
Soda	11.95	10.13
Lime	14.45	14.02
Boracic acid . .	34.71	36.91
Chlorine	1.34	1.33
Sulphuric acid .	1.10	0.50
Silica	0.60	..
Sand	2.00	..
Phosphoric acid .	Traces	..
Alumina	..	..
Magnesia	..	..
	100.00	100.00

The difference in the quantities of water, as shown in these two analyses, is owing to the gradual loss of water by soda-salts when exposed for some time to the air.

By neglecting the accidental elements and calculating the water, soda, lime, and boracic acid, we arrive at the formula:—

The presence of the other substances given by analysis seems to indicate that this mineral has been formerly deposited by mineral springs; and the fact that the biborate of soda it contains has crystallised with ten equivalents of water, shows that the temperature of these springs could not have been greater than + 55° Centigrade. As it is imported from America for industrial purposes, tinkalzit contains about 60 per cent. of borax, 25 per cent. of borate of lime, and 2½ per cent. of common salt. It forms an excellent flux for metallurgic purposes, and has been employed with success in the porcelain manufactory of Sèvres by M. Salvétat. In fact, it appears capable of effectually replacing borax in all the applications of this rather expensive salt to industrial or manufacturing processes.

To extract boracic acid from tinkalzit a given quantity of hydrochloric acid is diluted with water and saturated, while boiling, with the pulverised mineral; the clear solution is decanted while hot, and upon cooling the liquid throws down the boracic acid in large quantities.—*The Technologist*, Sept., 1861.

TECHNICAL CHEMISTRY.

The Deodorisation of Sewage at Exeter.

At the last Monthly Meeting of the Local Board, Mr. Pince said, in addition to the report which he had to make, as Chairman of the Committee appointed to investigate the plan for disinfecting the sewage, he had received a very satisfactory letter from Mr. Margery, Engineer to the South Devon Railway, who said he had used the carbolic acid which Mr. Pince had supplied him with, with effect in horse-boxes and fish-vans. He had also received another letter from Dr. Kingdon, of the St. Thomas Lunatic Asylum, to whom a bottle of the disinfectant was sent, requesting him to use it in the most offensive parts of the Institution. The Doctor bore testimony to the high qualities of carbolic acid as a deodorising agent, and that having used it for some time he had found its effects to be instantaneous. In addition to these letters, he had to state that on Friday evening he attended, with Mr. Farrant and their Surveyor, at the depôt, and they had tested the sewage in the same kind of manner as other members of the Board had previously done. They proceeded to a place where there was a low level, and which was covered over with a thick scum. They scraped off a portion of this, and Mr. Farrant tested it. All of them smelt it, and nothing could be perceived but a rather pleasant smell of carbolic acid. That was highly satisfactory as far as Mr. Ellis and himself were concerned, and was fully confirmatory of the evidence adduced by the rest of the Committee. The letter of Mr. Farrant was to the effect that he had tested the sewage, as mentioned, and could not detect the slightest trace of noxious effluvia. He considered the present system of deodorisation most perfect. Mr. Ellis, the Surveyor, then read his report. Having stated that the three months proposed for the experiment of deodorising the sewage had expired, Mr. Ellis proposed to offer a few remarks on the subject:—

"The treatment of the sewage must necessarily be taken under two heads,—first, its disinfection, so as to render it free from smell and prevent it causing any nuisance; secondly, to utilise it, in order to make it remunerative to the Board. The average quantity of carbolic acid used per day, since its commencement, has been about one gallon, at a cost of 11d., diluted with lime-water in the proportion of about 1 in 250, and applied to the sewage about ten hours per day, Sundays excepted. The result, I have no hesitation in saying, has been most satisfactory. . . . The action of the disinfectant on the sewage is not, as many suppose it to be, of a temporary character,—viz., to abate and destroy smells for a time only, but, on the contrary, the carbolic acid possesses considerable power to disinfect, through staying, or, rather, preventing decomposition, which prevents the sewage becoming putrescent and giving off offensive emanations, or again reverting to its former state; and when the sewage is once disinfected at the depôt, or in any part of the sewer, it matters little how long it takes passing off; decomposition cannot again set in, nor can any noxious gases be afterwards evolved in the atmosphere. Through the application of the disinfectant upon the sewage being previous to the commencement of decomposition, ammonia is not formed, but becomes locked up and preserved in the sewage, both in the liquid and solid state, which necessarily enhances its value very much in an agricultural point of view. This is of the utmost importance, as it also renders the sanitary

state of the atmosphere in the immediate neighbourhood where the sewage passes comparatively pure, the carbonate of lime having answered the purpose of disinfecting the sewage, during the past three months of summer, and by the use of, on an average, about one gallon of carbolic acid per day, at a cost of 11d., whilst the quantity required to produce the same effect in winter, with the atmosphere at a low temperature, would be about two-thirds that quantity. Thus, estimating six months of the year at one gallon per day, at 11d. per gallon, and say 1½d. per day for lime, would give a cost of 18. 0½d. per day, or, for the six months, of 7½. 10s.; whilst for the remaining six months the price will be 5½., giving the cost of the disinfectant for one year at 12½. 10s. The superintendence of the man, at 10s. per week, interest on outlay, and wear and tear, say 1½. 10s. per annum, will give a total of 40½. per annum. . . . The disinfecting being satisfactorily overcome, the next and very important part, that of utilising the sewage and rendering it remunerative to the Board, requires attention. First, in order to utilise the sewage, it is of course necessary to procure the assistance of the owners of the property through which the sewage passes; and were they sufficiently acquainted with its value, it would not have flowed to waste so long unheeded; but as prejudice is frequently a barrier to improvements of this kind, it necessarily becomes a work of time to undertake and carry it out, however much its merits are known and appreciated. And previous to the application of the disinfectant several objections offered themselves in preventing its being undertaken as a whole, which now no longer exist: First, from the land immediately below the dépôt, and through which the sewage passes, belonging to several owners, some difficulty was experienced in obtaining the sanction and assistance of the whole; but there would be no difficulty in that respect, as the whole may now be taken by Lord Devon and Sir Lawrence Palk, who are, I believe, both favourable to the scheme. Secondly, before the sewage became disinfected, it was thought necessary to apply the whole of it to the land at all times of the year, but which is now indispensable, as at certain times of the year the sewage, when disinfected, might be allowed to pass down the course, as at present, and be carried off without any additional expense than that of disinfecting, which would be self-acting. Thirdly, another important advantage offers itself, which is the increased value of the sewage, after being disinfected, by looking up and retaining its manurial qualities until absorbed by the soil. . . . I believe no difficulty whatever would be experienced in getting a sufficient number of shares taken up by practical persons who have long since perceived the desirability of facilitating and grappling with a question so considerably discussed and possessing such national interest,—viz., that of returning to the soil those beef-growing properties which are well known to exist in the sewage of our towns, instead of allowing it to empty into and pollute our rivers. As such a step would, in my opinion, be a stepping-stone to the utilising the whole of the sewage of Exeter, as I have no doubt but that our neighbours on the opposite side of the Exe will, at no very distant period, not only from the interest they will feel in improving the sanitary state of the neighbourhood where their sewers empty into the river, but also to recognise and remedy the great agricultural waste which at present exists,—a waste which could be easily obviated and turned to a very profitable account."

Mr. Pince said, with regard to the fertilising qualities of the sewage, he wished to state that he had procured a

barrel of it, after the application of the carbolic acid. He spread the contents of the barrel over a poor, hungry piece of land, about an inch and a quarter thick. This he did on Thursday night, and after he had spread it he went out and knelt down, and no smell existed. On Friday afternoon he sowed three drills of mustard and three of rape. On Monday morning the seed was up vigorously, showing how actively stimulated it had been by the manure. Now it was broadly in leaf, which was quite black, and he should be happy to show it to any person. If he had had recourse to stable dung he must have spread it ankle-deep in order to have produced such an effect. He believed that those who had previously tried to utilise the sewage had expected too much from it. They had expected that a little would have acted like guano, but this was not so. If, however, it was spread over the land in a fair way, he believed it would have the same beneficial effect as it had had on his land. He did not wish to take the sewage away from the dépôt, because it might be said that he was an interested party, but this he could say, that if it was desired he should be happy to have it. Mr. Ellis, in reply to a question, said he had no hesitation in saying that the value of the sewage was considerably improved. The ammonia in escaping caused the smell, and the disinfectant arrested the ammoniacal qualities of the sewage. Mr. Pince said that the man at the dépôt, who was scientifically ignorant of the disinfectant, spoke of the altered appearance of the sewage after the disinfectant was applied. He said it was "yeasty-like," and that was so. Mr. Bradbeer said he had noticed the same appearance in the sewage. Mr. Dyer said the ammonia in it was fixed; it was not like guano, the ammonia of which was always evaporating. Mr. Bradbeer said that, as far as the experiment had gone, it had proved successful, but next came the question of expense. Mr. Ellis stated that, including the attendance of the man, the expense per annum would be about 38½. 10s. Mr. Pince said that at present the experiment had been conducted in its rudest form; but if it was made self-acting, as it would be, then the expense would be considerably reduced. After some further discussion with respect to utilising the sewage, Mr. Pince said he had received a letter from the Earl of Devon, who said that as soon as he returned from London he should have great pleasure in visiting the dépôt, and see it, with a view to the ultimate disposal of the sewage. He (Mr. Pince) was sure that the noble Earl was perfectly earnest about the matter. He would now ask the Board to continue the disinfecting process for a specified time, until some plan was devised for utilising the sewage; and in the meantime he urged the members to unite with him for the purpose of seeing if they could not make a profit of the sewage, and if not to get rid of it without loss or nuisance. The scavenger wanted to cart it away at an expense to the Board, which ought not to be. Mr. Dyer was asked to take the sewage, but that gentleman said he had not time to attend to it. Mr. Pince then repeated his former offer in the same terms, and observed that he thought the reason why Mr. Dyer had failed in his attempt to utilise the sewage was because he had tried to make it into an artificial manure, whereas it should be used in its natural state. Mr. Dyer said he had sent some of his manure to a gentleman at Southmolton, and it having been used for turnips, the gentleman said he had never had a better crop in his life. Mr. Bradbeer said, as the former experiment had been effectual, and as Mr. Pince wished the Board to back him up by continuing the experiments for a certain time longer, so as to see in the meantime what terms they

could make with the landowners, he had great pleasure in proposing that they do continue their present system for a twelvemonth longer. They could also in the mean time appoint a day to meet a committee of the South Devon Directors. It was then resolved, after further discussion, on the motion of Mr. Pince, seconded by Mr. Snow, that the disinfectant operations be continued for another year.

NOTICES OF BOOKS.

The Retrospect of Medicine: being a Half-yearly Journal containing a Retrospective View of every Discovery and Practical Improvement in the Medical Sciences. Edited by W. BRAITHWAITE, M.D., &c. &c., and J. BRAITHWAITE, M.B. Vol. XLIII. January to June, 1861. London: Simpkin, Marshall, and Co.

ANY Chemist who has felt the want of an Annual Retrospective View of every discovery and practical improvement in Chemical Science—and what English Chemist has not?—will be able to form some idea of the value of a work like this to the medical practitioner. The book is, of course, a compilation from the various medical journals, from which, all relating to the science and practice of medicine and surgery that is worth perpetuating, is brought together, systematically arranged for easy reference, and reduced to a readable compass. It cannot pretend to supersede the weekly periodical, which is, indeed, a necessity for it, as well as for every man who wishes to keep perfectly *au courant* with the progress of science. The object of the Editors is rather to fix in a more stable form the valuable matters which are to be found, necessarily associated with much that is comparatively worthless, in the pages of the weekly publications. This process of precipitation and filtration it is acknowledged the Editors carry on with much skill; and how much the service is appreciated by the profession is shown by the fact that the *Retrospect* has now reached its forty-third half-yearly volume.

The present volume is enriched by a condensation of Dr. Pavy's valuable Lectures on Diabetes, from which we make an extract relating to the testing for sugar in diabetic urine. After reviewing the different tests for grape sugar, Dr. Pavy gives the formula for the preparation of a cupropotassic liquid which he prefers to those of Barreswil and Fehling. The composition of this liquid is as follows:—

" Sulphate of copper . . .	320 grains.
Tartrate of potash (neutral) . .	640 "
Potassa fusa . . .	1280 "
Distilled water . . .	20 fluid ounces.

Dissolve each in a separate portion of the water, then mix the sulphate of copper and tartrate of potash, and afterwards add the alkali."

The above liquid "is of such a strength that 100 minims of it are exactly decolorized by half a grain of the purest well-dried grape sugar." Dr. Pavy then describes the method he adopts in quantitatively estimating the sugar in diabetic urine,—"100 minims of the blue liquid are taken, and a mixture of one part of urine, with five parts of water (because the urine is too concentrated alone) allowed to fall into it, drop by drop, whilst kept boiling in a small porcelain capsule, over the flame of the spirit lamp or gas. As soon as the blue colour of the copper solution has been completely removed, the operation is at an end. The amount of diluted urine employed, can be read off, and will contain an equivalent to half a grain of glucose." The Doctor reviews at some length, the objections to both the copper and the fermentation tests, neither of which, he shows, can be relied on as giving an infallible indication of the presence of sugar.

The following "*New Salt of Iron and Quinine*," as it is called by Dr. Fergus, may be new to our readers, and is we dare say a very useful compound. It is composed of 80 parts sulphate of magnesia, 15 parts sulphate of iron, and 5 parts sulphate of quinine; or in a scruple 16, 3, and 1 grain of the respective salts. This mixture is quite unalterable in the solid state, and forms a perfectly clear solution, remaining so for an indefinite period. The proportion of quinine may be increased if necessary, an additional quantity being readily soluble in a solution of the salt.

There are many papers of great value and some of rather startling novelty, in this volume, witness that one, utterly destructive to a bilious man's faith in a blue pill, showing that mercury has no specific action on the liver.

We wish we could have to record the publication of a *Retrospect of Chemistry* as useful to Chemists as this *Retrospect of Medicine* must be to Medical men.

NOTICES OF PATENTS.

479. *Fire Places.* W. DRAY, Farningham, Kent. Dated February 25, 1861.

THIS invention has for its object the more complete combustion of fuel and the prevention of smoke. The grate or fire-basket is constructed of a cylindrical or spherical form, and is capable of being revolved or turned on pivots, trunnions, or otherwise, so that the gaseous and carbonaceous products evolved immediately after the addition of a fresh supply of fuel may be caused to pass through the hot fire, which by half rotation has been brought above it, and in this manner the consumption of the greater part of the smoke secured.

Such a fire would probably require a little attention to maintain uniformity of heating; its construction, however, is calculated to aid in preventing smoke, and is in principle somewhat similar to the smokeless grate which is fed from below.

505. *Artificial Stone and Cement.* F. RANSOME, Ipswich. Dated February 27, 1861. (Not proceeded with.)

THIS invention is a modification of similar processes for which patents have on previous occasions been granted to Mr. Ransome. For the manufacture of artificial stone the inventor proposes to employ crushed or powdered chalk, which, after being saturated with silicate of soda solution, is moulded into shapes or blocks; then freely exposed to air to allow the material to become dry and hard. The surfaces are then repeatedly washed over with a solution of chloride of calcium to induce the formation by double decomposition of silicate of lime, so that the pores of the mass may be filled with a mineral substance, and, when finally dried, constitute a kind of artificial stone of great durability, and to a certain extent impervious to water. It is proposed to apply the same materials for coating or plastering walls, ceilings, &c.; and by way of enumerating other substances which are equally applicable to these purposes, the inventor claims the use of either of the soluble alkaline silicates in conjunction with quick lime, any one of the soluble salts of the alkaline earths, or the chloride of aluminium or iron.

The processes referred to in the specification have been frequently the subject of experiment and discussion ever since the first announcement of M. Fuchs's original researches. The early objection has not perhaps up to the present time received a satisfactory answer. This relates to a tendency of the chloride of sodium, formed as the secondary product in the double decomposition, to give rise to a kind of efflorescence which impairs, and ultimately destroys, the outer surfaces of the stone by exfoliation.

634. *Improvements in Preventing Incrustation in Steam-Boilers, and in Tanks for Containing the Feed for the same.* J. FARRER, Clapham, Surrey. Dated March 13, 1861. (Not proceeded with.)

WITH the intention of preventing the formation of calcareous incrustation in steam-boilers, the inventor proposes to employ either rain or distilled water for feeding the same. In order then to collect and store a sufficient supply of rain-water for this purpose, it is recommended to construct large tanks for its reception, lined with non-absorbent bricks, united with hydraulic cement, or with water-resisting cement alone.

The applicability of distilled water to these purposes is out of the question, since it involves the consumption of at least a double proportion of fuel to generate but one equivalent of steam. Rain-water could be advantageously employed if it were possible to command a sufficient supply, and by so much as the ordinary well or river water is diluted with rain-water, so will the thickness of the incrustation in the boiler be diminished, but this mode of proceeding resolves itself merely into the common practice of draining the roof into the water-tank from which the engine draws its supply.

Grants of Provisional Protection for Six Months.

1722. William Pask, Lydney, Gloucestershire, "Procuring a colouring matter from the refuse of iron stone, called 'colour spert.'"—Petition recorded July 6, 1861.

1776. Thomas Cobley, Meerholz, Hesse, Germany, "An improved process for the production or manufacture of fluo-silicates of tin, zinc, and baryta, and their application as pigments for glazing, enamelling, and in the manufacture of glass."—Petition recorded July 15, 1861.

1790. Joseph Pierre Gillard, Paris, "Improvements in the manufacture of soda, carbonate of soda, and hydrochloric acid, and in apparatus connected therewith."—Petition recorded July 16, 1861.

1826. Constantine Nicolaus Kottula, Holborn, London, "Certain new compositions to be used in the manufacture of soap."

1840. William Edward Newton, Chancery Lane, London, "Improvements in engines for obtaining motive power by an explosive mixture of inflammable gases and air."—A communication from Francisque Million, Paris.—Petitions recorded July 22, 1861.

1885. James Robertson, Park Street, Mile End, London, "Improvements in apparatus for the treatment of bodily pain with hot water, steam, hot air, and the like."—Petition recorded July 27, 1861.

1910. Horatio Mearing, Great Randolph Street, Camden Town, London, "An improved lucifer match and prepared paper for igniting the same."—Petition recorded August 1, 1861.

2026. William Wilds, Hertford, "Improvements in apparatus for ventilating."—Petition recorded August 14, 1861.

2023. John Cowdery Martin, High Street, Barnes, Surrey, "An improvement in treating bones, and the manufacture of the products thereof."—Petition recorded August 15, 1861.

2053. William Bennett, London Street, Paddington, London, "A new and improved composition to be used as fuel, and in the lighting of fires."—Petition recorded August 19, 1861.

2110. Richard Arohibald Brooman, Fleet Street, London, "An improved method of treating the hop plant to obtain a material resembling wool."—A communication from Barthélemy Picard, Nancy, France.

2142. Benjamin Browne, King William Street, London, "An improved process for concentrating ores or tailings or separating pulverised mineral substances of different kinds or qualities from each other."—A communication

from Henry Eberhard Roeder, Broadway, New York, United States.

2159. Alexander Taille, Agen Lot et Garonne, France, "An improved manufacture of manure."

2161. Henry William Spencer, Stepney Causeway, Commercial Road, London, "Improvements in the manufacture of animal oils, the said improvements relating more particularly to the processes of refining them to be used for lubricating purposes."

2191. George Knight, Foster Lane, London, "Improvements in giving lustre to written and printed letters, figures, and devices."—Petitions recorded September 2, 1861.

2031. John Bethell, King William Street, London, "Improvements in the manufacture from steatite of journals, axle-boxes, and bearings for machinery, axles and spindles; in making smoking pipes, buttons, crucibles, and pots for chemical and smelting purposes, and also of a lubricating compound for railway and other carriages."—Petition recorded August 15, 1861.

2196. Patrick Robertson, Sun Court, Cornhill, London, "Improvements in treating yeast, and in the manufacture of ammoniacal salts and a substitute for animal charcoal."—Petition recorded September 3, 1861.

2213. Frederick Bennett, Upper Works, Bagillt, Flintshire, "An improved method of coating the interior surface of lead and lead composition pipes with tin or its alloys."

2229. Charles Felton Kirkman, Palace New Road, Lambeth, "Improvements in obtaining manure from sewage and in the apparatus employed therein."

2262. Marc Antoine François Mennons, Rue de l'Echiquier, Paris, "An improved combination of chemical and mechanical processes for the conversion of fibrous vegetable matters into paper-pulp."—A communication from Louis Achille Carteron, Dieuze, Meurthe, France.—Deposited and recorded September 12, 1861.

Notices to Proceed.

1163. Raoul Bernard, Bordeaux, France, "Improved means of catching flies."

1166. John Rolfe Hunt, Chichester Place, Wandsworth Road, Surrey, "Improvements in the manufacture of gutta-percha, and compounds thereof, with other matters and substances."

1200. Auguste Cesar Achille Gerard de Melcy, Paris, "An improved treatment of natural phosphate of lime for several purposes."—Petitions recorded May 11, 1861.

1207. Francis Puls, Francis Terrace, Hackney Wick, Middlesex, "A mode of preparing an oxidising agent."

1231. John Henry Johnson, Lincoln's Inn Fields, London, "Improvements in apparatuses for the manufacture of aerated waters, and in vessels or receptacles for containing the same."—A communication from Jean Louis André and Philippe Ferdinand Guillot, Paris.—Petitions recorded May 14, 1861.

1276. Frederick Oldfield Ward, Hertford Street, May Fair, London, "Improvements in manufacturing manure, and in obtaining accessory products."—Petition recorded May 8, 1861.

1955. Alcidaïs Auguste Romain Damoiseau, Paris, "Improvements in apparatus for drawing blood or other fluids from the human or animal body."—Petition recorded August 6, 1861.

1214. Thomas Bell, Usworth House, Gateshead, Durham, "Improvements in the decomposition of the compounds of aluminium and in coating metals with aluminium or its alloys."—A communication from Louis Le Chatelier, Paris.—Petition recorded May 13, 1861.

2221. John Reid, Leith, Mid-Lothian, North Britain, "Improvements in the treatment of gas and the apparatus employed therein with a view to its more accurate measurement in wet gasometers."—Petition recorded September 5, 1861.

CORRESPONDENCE.

On the Theory of Three Primary Colours.

To the Editor of the CHEMICAL NEWS.

SIR,—I am somewhat surprised that all your readers have passed over in silence the paper of Professor J. C. Maxwell, contained in the CHEMICAL NEWS of June 29, on the theory of three primary colours. As I believe he is in error on two or three points, and especially when he affirms that red, green, and blue are the primary colours, perhaps you will kindly allow me to make a few observations on the subject. Mr. Maxwell says that "experiments with pigments do not indicate what colours are to be considered as primary." This he says apparently because "the colours of a mixture of pigments are often very different from a true mixture of the colours of the pure pigments," and because the "green tint produced by mixing most blue and yellow pigments" is unsatisfactory. But the colour resulting from the combination of some of the colours of the solar spectrum is often very different from the intermediate colour of those employed, as well as those resulting from a mixture of coloured bodies; and the reason why some blue and yellow bodies do not produce a pure green is capable of satisfactory explanation. Mr. Maxwell remarks, that "by mixing chrome and ultramarine we get all hues of green." But these bodies are generally not adapted for producing green, because most of the ultramarine has a violet tint, and the chrome an orange one. When we wish to produce a pure colour from a mixture of two others, it is necessary to select either pure colours or, perhaps still better, those which are of the tint of the colour which we desire to obtain. By proceeding in this manner we shall never fail to get pure colours. There are bodies of a crimson colour, and others which are scarlet. The first is a red with a violet hue, and the second is a red with an orange hue. Now, when we wish to obtain a violet colour, we combine a crimson colour with a blue one; but when we wish to produce an orange colour, we mix a scarlet colour with a yellow one. If in the latter case we employ a body of a crimson colour, an orange colour is not produced, but a buff; and if Mr. Maxwell has not been very careful to procure coloured bodies of the proper tint, we need not be surprised that he has failed to obtain satisfactory results, and that he disapproves of the use of pigments and mixtures in determining which are the primary colours.

Evidently coloured bodies form the basis for a sound decision upon this subject; and I cordially agree with the generally received opinion, that red, yellow, and blue are the primary colours, because all colours of bodies can be produced from them, while those colours of bodies cannot be produced from any, and because, as every prismatic colour can be formed by combining the colours of the spectrum, we cannot so readily ascertain by experiments with them which are the primary colours.

Presuming, then, that red, yellow, and blue, are what are known as the primary colours, though it is not meant to include any theory of the manner of their production by the prism. I will attempt very briefly to show that this view is confirmed by experiments with the prismatic rays, in order that it may not be necessary to admit the incongruous statement of Professor Maxwell that red, yellow, and blue, are the primary colours for pigments, while red, green, and blue, are the true primary colours as determined by experiments on the prismatic spectrum. There are three different effects produced when coloured rays of light are superposed:—

1. When all the colours of the spectrum are combined, all colour is destroyed; as it may be also by the superposition of two or three of those colours which would produce the prismatic colours in about the same relative proportion as they are found on the spectrum.

2. When some of the coloured rays are superposed, no colour is destroyed, as in the formation of orange, green, indigo and violet from red, yellow, and blue.

3. When other colours of light are combined, a portion of colour is destroyed and a portion remains, as is always the case when red, yellow, and blue, are produced from the other colours.

This occurs because for colour to be destroyed, the colours combined must be of a certain tint or united in certain proportions, and if one of them be in excess, colour will be produced.

If this is true, it divides the prismatic colours into two classes; and that the division is correctly made, is exceedingly probable, because no one who is theoretically and practically acquainted with colour, can deny that when orange, green, indigo, and violet, are produced by the combination of two of the three colours, red, yellow, and blue, that the sensation of colour produced is a compound of the sensations which the two colours produce separately; and on the contrary, that when red, yellow, and blue, are produced from two of the other four colours, that the sensation produced is not a compound of the sensations which the two colours produce separately. I, therefore, conclude that this natural division of red, yellow, and blue, into one group, and of orange, green, indigo, and violet, into another, and its being the same division as we make of coloured bodies, is a sufficient reason why yellow should still be considered a primary colour.—I am, &c.

J. J.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Quadrachloride of Iodine.—Dr. H. Ksemmerer (*Journ. für Prakt. Chem.*, Bd. lxxxiii. s. 21) noticed some small, red, well formed octohedral crystals, which had separated from some fluid chloride of iodine that had been kept in a sealed tube for about six years. These he at first took for an allotropic modification of the chloride; but analysis showed that they contained four atoms of chlorine to one of iodine, and were consequently an hitherto unrecognised compound of those two bodies. Their formation is explained by the equation $4\text{ICl} = \text{ICl}_4 + 3\text{I}$, the iodine remaining dissolved in the mother liquor of the crystals.

Bromine Compounds of Molybdenum.—C. W. Blomstrand describes these (*Journ. für Prakt. Chem.* Bd. lxxxi. s. 433). *Bromide of Molybdenum* (Mo Br_2), formed by passing bromine vapour over metallic molybdenum strongly heated. Oxybromide is first formed, then a greyish-green sublimate of sesquibromide, and lastly some yellow bromure. A few dark-coloured crystals of the bromide are found mixed with the preceding. The author has varied his experiments, trying various temperatures, and diluting the bromine vapour by varying proportions of carbonic acid, but never could get much of the bromide. It forms brilliant, black, well-formed acicular crystals, which are fusible, and give a brown-red vapour. They deliquesce in the air, and yield a black fluid, give a brownish-yellow solution with water, from which alkalis precipitate a rusty yellow precipitate of oxyhydrate. By heating it is easily decomposed into the sesquibromure and free bromine, $2\text{Mo Br}_2 = \text{Mo}_2\text{Br}_3 + \text{Br}$.

Sesquibromure of Molybdenum.—(Mo_2Br_3) Formed as before, when bromine vapour is passed over metallic molybdenum, and also by the use of a mixture of the oxide and charcoal. It forms, at times, short blackish-green acicular crystals, but is mostly obtained in slender threads, like asbestos. By a strong heat it is decomposed into the bromure and free bromine. Under ordinary circumstances the sesquibromure has great stability. The threads made into a ball and thrown on water swim like a cork. It is not sensibly attacked by boiling hydrochloric

acid, nor by dilute nitric acid at the ordinary temperature. Dilute alkalis act on it slowly in the cold, and on boiling perfectly decompose it.

Bromure of Molybdenum.—(Mo Br , or Mo_2Br_2 , Br) Formed when the sesquibromure is heated to redness, and by the direct action of bromine in the metal. It is altogether insoluble in water and acids, but dissolves in boiling dilute alkalis, the yellow solution thus formed containing the bromomolybdous oxide united with an alkali, $\text{Mo}_2\text{Br}_2, \text{Br} + 2 \text{KOH} = \text{KBr} + \text{KO}, \text{Mo}_2\text{Br}_2, \text{O}$. The yellow solution, on standing, yields small, brilliant, orange-coloured crystals, of the compound $\text{Mo}_2\text{Br}_2, \text{O} + 9\text{HO}$. Saturated with carbonic or acetic acid, the hydrate, $\text{Mo}_2\text{Br}_2, \text{O} + 3\text{HO}$, is precipitated. The author notices another salt, the bioxybromide of molybdenum, formed in the same way as the corresponding chlorine compound lately described. It is obtained in orange-coloured scales of peculiar brilliancy, deliquesces in the air, and gives a colourless solution with water.

Composition of a Roman Mirror.—Souhay had the opportunity of analysing a fragment of a Roman mirror dug up near Mayence. It was of a greyish-white colour, brittle under the hammer, had a fine granular fracture, the fractured surfaces showing small holes filled with small metallic prisms. The sp. gr. = 9.21. The percentage composition was,—tin, 19.05; lead, 17.29; copper, 63.39. The alloy was probably made by melting together 1 part of tin, 1 of lead, and 3 of copper.—*Journ. für prakt. Chem.*, Bd. lxxii., s. 275.

Combustible Gas in a Salt Mine.—There is an opening in the deepest part of the Wieliczka mine, from which a stream of gas issues. When a light is brought in contact, the gas ignites, and a flame two or three feet long is seen. It quickly lessens, however, and soon goes out. Pebal (*Annal. der Chem. und Pharm.*, Bd. cxviii., s. 27) analysed the gas, and found it to be composed of

Nitrogen	65.47
Carbonic acid	1.18
Oxygen	12.90
Light carburetted hydrogen.	20.45

100.00

MISCELLANEOUS.

Telegraphic Night Signals.—On the evenings of the 24th and 25th ult. a series of experiments were made under the direction of Captain Bolton, for the purpose of ascertaining the capabilities of the lime-light as a means of communicating by signals between distant stations during the night. Southend and Sheerness were the stations selected, and, as the result of the trial, it was found practicable to hold correspondence by a system of time signals depending upon the alternate exhibition and screening off of the light. Notwithstanding the haziness over the water at the time, it was not difficult to interpret the indications on the opposite shores—the stations being distant from each other six miles. Further experiments are in contemplation to be carried out at Portsmouth over sea and land, when the *Excellent* gunnery ship will be provided with one of the signal lamps.

The Prevention of Railway Accidents.—With that keen attention to passing events which characterised his former management of the Polytechnic, Mr. Pepper has recently provided the visitors to that ever-attractive institution with a new lecture on the prevention of railway accidents, a subject which the recent catastrophes at Kentish Town and in the Clayton tunnel have invested with a fearful interest. The lecture was illustrated by numerous models and diagrams, among which may be mentioned those of Mr. Delafond's apparatus for the prevention of

accidents through attempts to enter or leave trains in motion, and Mr. Allen's electric bell and dial, for instantaneous communication between guard and driver. The great feature of the lecture, however, as bearing directly upon recent disasters, was a series of beautiful models of the safety kerb and life guards, patented by Mr. Wright, C.E. The former consists of a strong iron kerb, backed with earth, and of sufficient height to prevent locomotives or carriages from running off the rails, parallel to which the kerb is firmly fixed. In the case of the wheels mounting the rail, they rub against the kerb, and are turned on to the rail again directly, without the possibility of an accident. The life guards are strong pieces of iron, so affixed that, should a wheel or axle break, they rest on the kerb, supporting the carriage, and, by their grating, warning the guard, while they act also as a drag. Some beautiful photographs of the new International Exhibition building, produced by Messrs. Birnatingle, were shown, after the lecture, by Parr's new electric lamp.

Grocers v. Doctors.—A Company is, we understand, in progress of formation, to be called "The Equitable Grocery Consumers' Company;" and its object is—at least, so says the programme, 'to supply the public with all descriptions of grocery in a pure and unadulterated state.' Every pater- and materfamilias will feel deeply obliged to such an enterprising grocery establishment, provided only it will carry out punctually its promises. The benefits of it would reach very widely; for it would teach all other grocers to mend their wares. We have often adverted to the rascality of trade now pretty universally going on; and have also shown that the certificates of purity of their wares, as usually given by chemists and microscopists to the shopkeepers, are mere delusions, and worse than delusions. These certificates are, in fact, mere traps to catch customers; and we must say that those gentlemen who are such free dispensers of them are rather to be considered as abetting the tricks of the rascally shopkeeper than defending the public. Analyses of the kind we refer to are, in truth, scientific warrants, which may be, and often are, used as a cover or shield, under which vile goods are sold as superfine. Molasses of Oxford-street takes a specimen of his goods—we need not say Number One of its kind—to Dr. Singley, who, after due microscopical and chemical investigation of its nature, supplies Molasses with a certificate testifying that his specimen is perfect of its kind. Molasses bows and smiles, and thankfully pays his *honorarium*. He then repairs to his printer, and has a few thousand of the certificates struck off, and pasted on to the most villainous of wares. These wares then go forth to the world under the trumpet and patronage of the famous Professor Singley. We will say that on the very face of it, and in the way here described, our men of science in the analytic line are assisting rascally tradesmen in the distribution of their rascalities. May this Company teach and follow a better path.—*Brit. Med. Journal*.

ANSWERS TO CORRESPONDENTS.

F. W. G.—The complete researches are not yet published. We will give an account of the experiments as soon as possible.

J. J.—The paper was received with thanks.

A Reader.—The methods of calculating formulae of chemical compounds from the per-centage composition are given in a very complete manner in the last edition of *Frobenius' Quantitative Analysis*, published by Churchill, pp. 452 to 476.

C. R. C. Tichborne.—Received with thanks. A proof will be sent.

Alfred Peile.—We do not know the price. The book is published by Baillière, Regent Street.

THE CHEMICAL NEWS.

VOL. IV. No. 97.—October 12, 1861.

THE PRESERVATION OF BUILDING STONE.

(Continued from page 181.)

July 17, 1861.

Sir,—Having been requested to submit to the Committee our opinion on the nature and causes of the decay of building stones generally, and of the stone employed in the construction of the New Houses of Parliament in particular, we now have the honour to submit the following observations:—

Building stones in general may be divided into two classes:—

1. Those which consist of materials not easily acted upon by acids.
2. Those composed of materials which are, partially or entirely, acted upon by acids with facility.

As an illustration of the first class, granite porphyries and serpentines may be quoted, whilst to the second belong limestones, dolomites, and certain sandstones, containing carbonate of lime as cementing material.

The stone used in the New Houses of Parliament belongs to the second class of building materials, consisting, as it does, almost entirely of the carbonates of lime and magnesia. The following analyses of several varieties of dolomite by Professor Daniell and Messrs. T. Ransome and B. Cooper, are quoted in illustration of the general composition of the stone in question:—

	Bolsover Moor.		North Anston.		Woodhouse.	Steeple.

¹ The analyses by Daniell are quoted from the "Report of the Inquiry undertaken under the Authority of the Lords Commissioners

Regarded from a purely chemical point of view, the difference in the resisting power to corrosive agents of different stones would appear, at first sight, to depend entirely upon their chemical composition; but even a moderate acquaintance with the properties of the components of such building stones demonstrates that there are other conditions at least equally instrumental in determining the degree of permanence of different stones.

It is a well-established fact, that the same chemical substance exhibits, in different conditions, a great variation in its behaviour with chemical agents. Numerous examples might be quoted in illustration of this. Thus, marble and chalk are chemically identical, but, owing to the difference in their physical structure, the one being crystalline and the other amorphous, the former is much less readily acted upon by acids than the latter. Again, artificial peroxide of iron is readily soluble in acids; peroxide of iron, in the form of hæmatite, is attacked with difficulty by acids; and the same oxide, after exposure to a powerful heat, is almost entirely insoluble in acids. The influence of aggregation in these instances, and in numerous others which might be quoted, is obvious and generally admitted by chemists, however different and imperfect may be their views regarding the connection between physical condition and chemical effect.

The observations just made regarding the behaviour of substances, such as enter into the composition of building stones, cannot but apply with equal force to the aggregates of such components,—to the building stones themselves.

The atmospheric influences to which building stones are subject are many of them essentially chemical actions, involving processes analogous to, or identical with, those performed in the laboratory, although, from the extreme dilution of the chemical agents, as existing in the atmosphere, they must necessarily be of a very gradual character.

There are few instances in which the influence of the state of aggregation upon the permanence of a building stone is more apparent than in that of the dolomitic limestone, used in the construction of the New Houses of Parliament. Here, in one and the same block of stone, of comparatively small dimensions, we find certain portions of the surface powerfully disintegrated, while others appear in a perfectly sound condition. Chemical analysis has hitherto failed to establish any important difference in the composition of sound portions of such stones and those parts which are subject to decay; it is, therefore, legitimate to attribute the unequal permanence of the stone, under atmospheric influences, to such

of Her Majesty's Treasury, by C. Barry, Esq., H. T. De La Beche, Esq., W. Smith, Esq., and Mr. Charles Smith, with reference to the Selection of Stones for Building the New Houses of Parliament." Those by Ransome and Cooper are extracted from a paper "On the Composition of Limestones used for Building Purposes, especially on those employed in the Erection of the New Houses of Parliament," contained in vol. II., part II. (1848) of the "Memoirs of the Museum of Practical Geology."

structural differences as may be comprehended under the term, "state of aggregation."

Before proceeding to an examination of the particular character of the decay observed in the stones of the New Houses of Parliament, it may perhaps be desirable to glance at the nature of the changes to which building stones generally are subject under atmospheric influences. Under normal conditions these changes must be ascribed to the action of the oxygen, carbonic acid, nitric acid, and water in the atmosphere. In the air of towns, however, there are certain other constituents, such as several acids of sulphur, and occasionally hydrochloric acid, which cannot fail to exert an additional disintegrating influence upon building stones.

The action of oxygen must be of comparatively a subordinate character, its effects being confined to constituents which occur but rarely, and generally in limited proportions, in building stones, such as the sulphides of iron, and the protoxides of iron and manganese; these compounds, being very prone to oxidation, would tend to disintegrate the stones by the absorption of oxygen. Of far greater importance are the effects of carbonic acid and water. Carbonic acid, in the presence of water, is a powerful solvent; it not only corrodes the calcareous and magnesian carbonates (more or less powerfully according to their state of aggregation), whether they form the principal constituents of the stone or are only present as cementing materials, but is capable even of attacking and gradually decomposing the hardest and most indestructible rocks.

In the case of the calcareous and magnesian constituents of stones, carbonic acid acts by transforming the insoluble earthy carbonates into soluble bicarbonates, which are thus removed from the substance of the stone; whilst its influence on silicious rocks consists in the elimination of the alkaline bases, in the form of carbonates, and the separation of the silica in a more or less friable condition. The weathering of granites, and their gradual transformation into the several varieties of porcelain clay, affords an interesting illustration of the latter kind of action. In the changes just mentioned, the carbonic acid and water are equally concerned; the water serving not only as a vehicle for the introduction of the carbonic acid into the pores of the stone, but also as a solvent for the products of its action. There are changes, however, to which building stones are subject, in which water is the sole agent, and which are more of a mechanical than of a chemical character. The expansion which water undergoes on freezing, and the irresistible force which it then exerts, are well known; it is obvious that water freezing within the pores of a stone must exercise a disintegrating action not less powerful than those above referred to.

Recent researches have demonstrated that nitric acid is a frequent and perhaps even a normal constituent of the atmosphere, and, as such, must undoubtedly assist in the destruction of magnesian and calcareous stone; but the proportions in which this acid has been found are so minute that it need not be dwelt upon as an important destructive agent. This remark, however, does not apply to the acids referred to above, as existing in the atmosphere of towns. The quantity of sulphur-acids in the air of towns, where a considerable amount of coal is consumed, is quite appreciable. According to the determinations of Dr. Angus Smith, the air of Manchester contains an average proportion, corresponding to one part of sulphuric acid in every 100,000 parts of air, which, in the centre of the town, rises to 25 parts in 100,000. No numerical data exist with regard to the

proportion of sulphur-acids in the London atmosphere, but it can scarcely be doubted that in the neighbourhood of the New Houses of Parliament they are present to an extent equal to the average amount found in the Manchester air; they must, therefore, be regarded as amongst the more important agents destructive to stone which are present in the London atmosphere.

A few observations remain to be offered regarding the particular nature of the decay manifesting itself in some of the stones of the New Houses of Parliament. It has already been pointed out that, so far as our experience goes, we are inclined to attribute the local character of the decay to structural differences obtaining in different parts of the stone. The general structure and the composition of the stone in the New Houses of Parliament render it moreover amenable to all the sources of disintegration which we have above enumerated, with the exception perhaps of oxygen, which can scarcely produce any appreciable alteration in dolomite. Thus, the chemical action of carbonic and sulphuric acids, in combination with water, will gradually dissolve and remove the carbonates of lime and magnesia, whilst the porous nature of the stone renders it liable to the mechanical effects of water under the influence of frost. The presence of sulphuric acid in the air of towns appears, in the case of magnesian limestone, to bring into play another process of destruction. This acid not only corrodes and renders soluble, as we have pointed out, the earthy carbonates (in which respect it resembles carbonic acid in its effects), but, forming with magnesia a readily crystallisable salt, the well-known sulphate of magnesia, remarkable for the large proportion of water of crystallisation which it fixes, it gives rise, in addition, to a mechanical destruction of the stone precisely similar to that produced by freezing water. The powerful mechanical effects resulting from the solidification of water, induced by crystallisation, are well known, although it would appear that they have not hitherto been sufficiently appreciated as auxiliaries in the process of disintegration of stone. The analogy between the solidification of water, by freezing and by crystallisation, is perfectly obvious, and a French chemist has suggested, as a means of recognising stones liable to disintegration by frost, to immerse them in a solution of sulphate of soda, and to note the subsequent effects of its crystallisation within the stone.

We have ourselves recently had occasion to observe some phenomena which go far to elucidate these destructive effects of crystallisation. The exfoliations exhibited by many of the fictile vases deposited in the British Museum were found to be due to the formation and crystallisation within the substance of the vessels of nitrate of lime. Again, in experiments on the preservation of fabrics by impregnation with saline substances, it was found that the crystallisation of sulphate of magnesia within the material produced a disintegrating effect upon the fibres, sufficient greatly to weaken the material.

In conclusion, we would remark, that the effect attributed to the crystallisation of the sulphate of magnesia, in assisting the decay of dolomitic stones, and more particularly of those used in the construction of the New Houses of Parliament, is borne out by the existence of a marked efflorescence of sulphate of magnesia upon those portions of the stone where exfoliation has taken place.

We have, &c.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Classification of Organic Substances by Series,
by JAMES SCHIEL, of St. Louis.

THE progressive series which, in 1842,¹ I introduced into organic chemistry, have become the chief means of classification, and of connecting organic substances generally. Several years after the introduction of the series, Gerhardt used them in the sense just mentioned in his "Traité de Chimie," and thereby contributed a great deal toward their general knowledge.² But the idea this distinguished chemist had formed of series was very imperfect, as is proved by the single fact that he ranged benzoic acid and acetic acid in what he called an isologous series ("Traité," t. i., p. 127). As in the present state of chemical science it is highly important that the principles of seriation be clearly understood, I will try to expound them in a more general and methodical manner than has been done hitherto.

The general formula of organic compounds containing carbon, hydrogen, and oxygen, is $C_n H_{2n+2} O_\gamma$. By giving, to γ successively the values 1, 2, 3, 4, . . . we may form the following series of oxidation:—

From this all the series necessary for the classification of organic substances may be derived by putting $\alpha = n$ and $\beta = 2n+2$, making β successively to decrease, the decrement being 2, 4, 6, 8, . . . By this we have the following series:—

and so forth.

Every general formula in one of these generic series represents special homologous series, the members of which have the difference $n \pm H_2$. When comparing the above series with the hydrocarburets known to exist in a free state, they will be found to represent different states of oxidation of these hydrocarburets.

Another kind of series is formed by making in the general formula $\alpha = n$ and $\beta = n$ and making β successively to decrease or increase, the increment or decrement being, 1, 2, 3, 4, . . . By this we form the series:

Every general formula here represents a series, the members of which are distinguished by $m \pm H$, and which I therefore call hemilogous series. It is to be remarked that a hemilogous series whose general formula is

can only exist when n is an odd number, as the number

of atoms of hydrogen entering into an organic compound is always an even number.³ The hemilogous series are very useful for comparing the physical properties of organic substances.

I will now apply these principles of classification to three large classes or groups of substances, the hydrocarburets, the alcohols, and the acids. The generic series formed by the first of these groups is the following:—

The maximum or minimum number of atoms of hydrogen which may be combined with n atoms of carbon cannot be determined at present, but there is no hydrocarburet known to contain more than $(2n+2)$ and less than $2n-(n+2)=n-2$ atoms of hydrogen to n atoms of carbon.

The alcohols form several generic series:—

Alcoholic series I.

Whether tetracid alcohols of the general formula

can exist, is not known, as we know nothing certain about the existence of tetrabasic radicals. The poly-ethylenic glycols of the general formulas

are bibasic alcohols corresponding to the type

Alcoholic series II.

Of this series the only member known as yet is allylic alcohol $C_3 H_6 O$ corresponding to the general formula $C_n H_{2n} O$.

Alcoholic series III. IV. V.

¹ *Annal. Liebig and Wöhler*, July number, 1842.
² Gerhardt changed the name progressive into homologous; in the discovery itself of the series he has no share.
³ If one atom of nitrogen enters into the compound, the atoms of hydrogen are an odd number, as nitrogen is triatomic. For this reason alone the formula of quinine, for instance, could not be written $C_{10} H_{12} N O_8$, as chemists formerly used to do, but $C_{20} H_{24} N_2 O_8$, as it is written now for other reasons.

The homologous series answering the general formula $C_nH_{2n-4}O$ is

C_6H_6O	phenylic alcohol	boiling point, 184°
C_7H_8O	benzoyletic	" " 204°
$C_8H_{10}O$	xyletic	" " 220°
$C_9H_{12}O$	(?)	" " "
$C_{10}H_{14}O$	cuminic	" " 243°

as homologous with phenylic alcohol, the last member of this series, cuminic alcohol, ought to boil at 264°.

Forming a hemilogous series out of such of those alcohols as answer to the general formula $C_nH_{n+1}O$, we have:—

C_7H_8O	benzoyletic alcohol	boiling point 204°
$C_9H_{10}O$	cinnamyletic	" " 250°

The difference in composition is here $2\Theta H$, the difference in boiling point 46°; to the difference ΘH in composition there corresponds therefore a difference in the boiling points of 23°, and as to the difference ΘH_2 we mostly find a difference of 19°—20° in boiling points, the influence of the atom of H on the boiling point is in this case 3°. In a similar manner the influence of Θ on the boiling point may be shown to be 26°, as benzoyletic alcohol and cinnamyletic alcohol differ by $\Theta + \Theta H_2$, and ΘH_2 answers to 20°, we have 46°—20°=26°. The influence of the single elements on the boiling point may thus be found by seriation and general laws deduced by comparing the different results obtained by this method.

(To be continued.)

On the Estimation of Tin by Standard Solutions, by M. SCHEURER-KESTNER, of Thann.

(Continued from page 102.)

FOR estimating the oxide of tin by permanganate of potash (or, what comes to the same thing, a solution of protochloride with the addition of carbonate of soda), I made use of the ingenious method M. Péan de Saint-Gilles¹ employed while studying the oxidising action of permanganate in alkaline liquids. This method consists, as is well known, in the joint use of permanganate of potash and protochloride of iron.

In making the following experiments a slight excess of carbonate of soda was added to the protochloride of tin, then an excess of permanganate of potash; and, lastly, ferrous chloride and acid.

Thus, the following are the standard solutions:—

Sn Cl. employed. Cubic centimètres.	Quantities of water.	Observed Standard.	
		With the protochloride.	With the protochloride.
2	400	14	14
2	500	14	14
2	600	14	12
2	700	14	10
2	1000	14	8
2	1500	14	5.5
2	2000	14	5
2	3000	14	4.2
2	3000	14	4

The small degree of affinity between oxide of tin and oxygen is made evident by passing a current of oxygen in a solution of protochloride of tin with carbonate of soda in excess. A solution containing 2 cubic centimètres of protochloride to 1000 cubic centimètres of water is unaltered, even though a rapid current of oxygen is passed through it for two hours.

The oxygen of water then has no influence on

protochloride of tin, and the results obtained are very regular, which explains why M. Lessens, by using an alkaline liquid, arrived at corresponding results.

This property might be of service in estimating the oxygen dissolved in water if the oxidation of the protochloride were not so slow. It is sometimes necessary to wait very long before adding the permanganate, until all the oxygen of the water is absorbed, which is always done after some time, as may be seen by the following experiments:—

Water.	Permanganate required by the Chloride of Iron.	Permanganate required by the Protochloride of Iron.	Permanganate required by the Protochloride of Tin.
1500	24	12.5	{ After quarter of an hour 13 After half an hour . . 13

We have seen that M. Stromeyer, by a happy modification, has reduced the estimation of tin to that of iron. Applying the same principle, a salt of copper may be substituted for a salt of iron. An equivalent quantity of copper can thus be estimated in place of tin; and M. Mohr's as well as M. Terrell's² experiments show that copper can be very exactly estimated by permanganate of potash.

A double decomposition takes place on protochloride of tin being added to nitrate or chloride of copper in excess; a salt of suboxide of copper forms, and the tin passes to the maximum state of oxidation, according to the following equation:—

To estimate tin, it is, then, sufficient to transform it into protochloride, to add to it a solution of nitrate of copper, slightly in excess, before diluting it with water, and to estimate the liquid obtained by permanganate of potash.

The following experiments show that, whether the operation is performed with nitrate of copper or whether we avail ourselves of oxidation in an alkaline medium, the results are the same:—

10 c. c. SnCl in 1200 c. c. of water required	52 of permanganate
10 ,, SnCl in 1200 c. c. of water, to which is added CuO.NO ₃ , required	87 ,,
10 ,, SnCl + NaOCO ₂ + SO ₃ + FeCl required	231 ,,
Deducting that needed for the salt of iron	144 ,,

Leaves remainder . . . 87 the salt of tin.

1.117 gr. of tin, obtained by the electrical means, were dissolved in hydrochloric acid and diluted with water sufficient to make the entire volume 200 cubic centimètres. 30 cubic centimètres of this solution required 9.2 cubic centimètres of permanganate, whether the operation is performed with nitrate of copper or with an alkaline solution.

¹ *Comptes-Rendus*, vol. xli., p. 230.

² For the estimation of copper, variable quantities of water can be used without affecting the results:—

Water employed.	Permanganate required by a reduced salt of copper.
0	16.3
100	16.4
500	16.3
1000	16.3
1500	16.4
2000	16.3
2500	16.4
3000	16.4

Permanganate was standardised by means of crystallised double sulphate of iron and ammonia $\text{FeO}, \text{SO}_4 + \text{NH}_4\text{O}_2\text{SO}_4 + \text{H}_2\text{O}$.

2.918 gr. of this salt required 24 cubic centimètres of permanganate. The salt containing 14.386 per cent. of iron, the 2.918 grm. of it contain 0.416865, or, rather, 1 cubic centimètre of permanganate = 0.017268 of iron, corresponding to 0.01818 of tin ($59\text{Sn} = 2 \times 28 = 56 \text{Fe}$.)

0.2 cubic centimètres of permanganate were required by 30 cubic centimètres of the foregoing solution of tin, making 0.16725 of tin.

Thus, we have:—

Tin taken	:	:	:	0.16755
Tin found	:	:	:	0.16725

Difference = 0.00030

By calculating the equivalent of tin by these data, and by removing the iron from it, we obtain 59.105, which differs little from 59.00, the number generally adopted.

The result of these experiments is, that by passing an oxygen current through a concentrated solution of protochloride of tin, the oxygen is not fixed; in diluted solutions, on the contrary, the oxygen is rapidly absorbed by the stannous salt. Oxygen does not act on hydrated protoxide of tin. The variations noted in the strength found when protochloride of tin is oxidised by permanganate of potash are not observed in concentrated solutions; they take place only in presence of oxygen dissolved in water.

There are three different processes for estimating tin by permanganate of potash:—1. To operate with water freed from air by boiling, protecting it from access of air while cooling. 2. To oxidise protoxide of tin in an alkaline medium. 3. To decompose protochloride of tin either by a salt of iron, as proposed by M. Stromeyer, or by a salt of copper.

On Ozone, Nitrous Acid and Nitrogen, by T. STERRY HUNT, F.R.S.

THE formation of a nitrite when moist air is ozonized by means of the electric spark (the old experiment of Cavendish), or by phosphorus was shown by Rivier and de Fellenberg, who concluded that the reactions ascribed by Schönbein to ozone were due to traces of nitrous acid. The subsequent experiments of Marignac and Andrews have, however, established that ozone is really a modification of oxygen, which Houzeau has shown to be identical with the so-called nascent oxygen, which is evolved, together with ordinary oxygen, when peroxyd of barium is decomposed by sulphuric acid at ordinary temperatures. The spontaneous decomposition of a solution of permanganic acid also evolves a similar product having the characters of ozone.

Believing that the nitrous acid in the above experiments is not an accidental product of electric or catalytic action, but dependent upon the formation of active or nascent oxygen, I caused a current of air to pass through a solution of permanganate of potash mixed with sulphuric acid. The air, which had thus acquired the odour and other reactions of ozone, was then passed through a solution of potash; by which process it lost its peculiar properties, while the potash solution was found to contain a salt having the reactions of a nitrite.

As I suggested in this Journal in 1848, I conceive gaseous nitrogen to be the anhydrid amid or nitryl of nitrous acid; which in contact with water might under

certain circumstances generate nitrous acid and ammonia. From the instability of the compound of these two bodies, however, it becomes necessary to decompose one at the instant of its formation in order to isolate the other. Certain reducing agents which convert nitrous acid into ammonia may thus transform nitrogen (NN) into 2NH_3 . In this way I explain the action of nascent hydrogen in forming ammonia with atmospheric nitrogen in presence of oxydising metals and alkalies. (Zinc in presence of a heated solution of potash readily reduces nitrates and nitrites with the evolution of ammonia.)

Now, an agent which instead of attacking the nitrous acid would destroy the newly-formed ammonia, would permit us to isolate the nitrous acid. Houzeau has shown that nascent oxygen is such an agent, at once oxydising ammonia with formation of nitrate (nitrite?) of ammonia, and thus when ozone (nascent oxygen) is brought in contact with moist air both of the atoms of nitrogen in the nitryl (NN) appear in the oxydised state.

From this view it follows that the odour and most of the reactions ascribed to ozone are due to nitrous acid which is liberated by the decomposition of atmospheric nitrogen in presence of water and nascent oxygen. We have thus a key to a new theory of nitrification and an explanation of the experiments of Cloez on the slow formation of nitrite by the action of air exempt from ammonia upon porous bodies moistened with alkaline solutions. I hope soon to send the results of my farther inquiries in this matter.—*American Journal of Science*, Vol. xxxii., No. 94.

On the Formation of Picramic Acid, by M. CAREY LEA.

IT is to M. Aimé Girard that we owe the first isolation of picramic acid, and correct determination of its constitution. His views, however, of the circumstances under which it is formed do not altogether agree with the results of my observations, and I advert to them now, because his second paper contains a criticism on the results obtained by another chemist, which criticism I think depends upon an inexact view of the reactions.

In a paper published by Dr. Evan Pugh, in Liebig's "Annalen," he endeavoured to establish the identity of picramic acid with Wöhler's nitrobenzamic acid. M. Girard, while he agrees with Mr. Pugh in his conclusions, rejects his experiments and reasonings as insufficient.

"This chemist, in fact," he says, "proceeded exactly as Mr. Wöhler had done before I demonstrated the formation of picramic acid by means of sulphydric acid. His process consists in mixing picric acid with proto-sulphate of iron, boiling with excess of baryta, precipitating the soluble baryta salt with ammoniacal acetate of lead, and finally in decomposing the lead salt by sulphydric acid. Now it is evident that under these circumstances, even supposing that the protoxide of iron had not converted the picric acid to picramic, the sulphydric acid alone would have produced this reduction."

At first sight this conclusion seems perfectly legitimate, so much so, that it is probable that no test by experiment was thought necessary. Had such been made it would have been ascertained that sulphydric acid is wholly without power to reduce picric acid whether free or in combination with lead, to picramic acid.

The fact appears to have been overlooked that sulphydric acid is quite incapable of producing this reaction either upon picric acid, or, as far as my experiments go, upon any picrate. It is the alkaline sulphides that possess this power, and not free sulphydric acid, a circumstance which has not been noticed, in consequence of chemists operating on solutions of picric acid in alcohol to which excess of ammonia had been added. When sulphydric acid is passed through such a solution, sulphhydrate of ammonia is formed and acts on the picric acid.

Sulphydric acid may be passed through solutions of picric acid, picrate of potash or picrate of ammonia, either at ordinary temperatures, or at a boiling heat, for any length of time, without producing the slightest effect. On the addition of excess of alkali the reducing effect of the sulphide formed is immediate.—*American Journal of Science and Art.*

On the Presence of Nitrates in Mineral Waters, and on the Production of Saltpetre, by R. HAINES, M.B., Professor of Materia Medica, Grant Medical College, Bombay.

(Continued from page 166.)

In confirmation of the above view, I will mention the result of an analysis of a nitre-yielding earth, which was sent me from Patree, in Guzerat,—the only substance of the kind I have had the opportunity of examining. It is said to occur in a space of limited breadth, extending from East to West, and not elevated. It was not a general sample of the soil, but the rich surface sweepings which contained the saline effluence. This earth contained the large proportion of 26.207 per cent. of soluble salts, the per-centage composition of which was as follows:—

Chloride of sodium	56.507
Nitrate of soda	24.126
Nitrate of potassa	8.631
Sulphate of magnesia	5.284
Sulphate of lime	5.452

100.000

Here it will be observed that although the total nitrates amounted to nearly 33 per cent. of the soluble matters, yet the nitrate of potassa was little more than a fourth of this, the greater part of the nitric acid being in combination with soda; and the disproportion is even greater than appears at first sight, as from the lower equivalent of soda, the nitrate of soda contains, proportionally, more nitric acid than that of potassa; the 24.126 parts of the former containing 15.327, the 8.63 of the latter but 4.615 of nitric acid. By the ordinary mode of crystallisation, the greater part of the nitrate of soda would remain in the mother-liquor, and be thrown away. The remedy is simple enough in theory,—viz., to add potash salts, or wood ashes, which always contain them, whence, by double decomposition, nitrate of potassa and a soluble salt of soda will be formed. I recommended a trial of this plan, but I have not heard anything of the result. It is the general practice in preparing saltpetre by the artificial method in Europe to add carbonate of potassa to the crude solution as long as a precipitate of carbonates of lime and magnesia is formed, or, what comes to the same thing, until the liquor acquires an alkaline reaction. The liquid contains the nitrates chiefly of these bases, and the cessation of the precipitation

marks the term of the decomposition; but when nitrate of soda is to be decomposed by these means, the manufacturer has no such guide to assist him. No precipitation occurs, and the first addition of potash renders the liquid alkaline, so that he must be content with noting the specific gravity of his crude liquor, and adding as much potassa as experience shall show him to be the minimum quantity requisite to increase the yield of nitre to the utmost. The most economical plan would appear to me to be, to add a portion of wood ashes to the earth under lixiviation; and then, when all the saltpetre has crystallised out in the ordinary way, to stir into the mother-liquors sufficient wood ashes to make the mass nearly solid, and to dry it with a pretty strong heat. The nitrates would thus be fully preserved in a portable, and not deliquescent form, and the extraction of the salts could be performed elsewhere; while, even if an excess of ashes were used, their potash salts could be made available by the manufacturer, and would be worth the carriage. I regret not having paid attention at the time to the insoluble matters. I have searched for recorded analyses of a similar kind, but, to my surprise, I have been only able to find two old ones, by Dr. John Davy. One of the surface earth of the saltpetre-producing cavern of Memoona, in Ceylon, the other of the saltpetre earth of Tirhoot, in Upper Bengal,¹ and one by Mr. Stevenson, also, of saltpetre earth from the Tirhoot district,² the latter being an average sample of the ordinary soil, while that analysed by Dr. Davy was from the rich surface collections.

	Analysis of earth.				100 parts of soluble salts consisted of		
	Memoona (Davy)	Tirhoot.		Memoona.	Tirhoot.

Total	100.0	100.0	100.0	100.0	100.0	100.0	

Lavoisier states that different samples of natural saltpetre in France yielded him, after treatment with potashes, from $1\frac{1}{4}$ to $5\frac{3}{8}$ per cent. of nitrate of potassa. Ragsky lately examined numerous samples of saltpetre earth (surface-sweepings) from Hungary, and found from 0.50 to 2.33 per cent. of nitrate of potassa. (In Hungary, an earth which yields 0.26 per cent. only, is said to be rich.) The most remarkable thing in Davy's analyses, given above, is the almost total absence of chloride of sodium, and, indeed, of all soda salts whatever. Another notable circumstance is, that the richest earths of France and Hungary cannot be compared for productiveness with the random samples of Indian earths.

On referring to Mr. Stevenson's paper, I find that it partly answers one of the questions that occurred to me, or at least gives some assistance towards answering it;

¹ Knapp's "Chemical Technology," i. 347.

² "Journal of Asiatic Society of Bengal," ii. (1833) 23.—"On the Manufacture of Saltpetre, as practised by the Natives of Tirhoot. By Mr. J. Stevenson, Superintendent Hon. Co.'s Saltpetre Factories in Behar."

and the statements are so much to the purpose, that perhaps I may be excused for quoting them:—

"The soil of Tirhoot almost everywhere contains a large proportion of saline matter, such as nitrate of potassa (saltpetre), nitrate of lime, sulphate and muriate of soda, &c.,³ but in general, the muriate of soda is most abundant. The saltpetre (as well as the other salts) lies in patches, as it were, some parts being more productive than others, according as carbonate of lime or sand alternately predominate. By analysing the different soils, I have found those places most productive of nitre to contain a redundancy of the former; and, on the contrary, where the soil was unproductive, I found a redundancy of the latter substance. I am, therefore, naturally led to the conclusion that carbonate of lime is one of the principal agents in the production of this article. This will also account for the district of Tirhoot being more productive of nitre than any other place in India, for almost half of its soil is calcareous."

Mr. Stevenson's observations, therefore, remarkably corroborate the views of Kuhlmann and others, as to the agency of carbonate of lime in nitrification; but, may we ask, is limestone essential? Cannot the nitric acid be formed and combine directly with potassa or soda, as well as by the indirect process suggested by Kuhlmann? Is there in potassa any peculiar property or affinity which makes the combination of nitric acid with it more frequently observed than that with soda? or is it merely that the collateral agencies which determine nitrification happen, by some combination of circumstances, to be more frequently present when there is potassa in the soil than when there is soda? or is the fact simply that nitrate of soda, when it does occur, is often overlooked altogether? Is limestone absent from the soils which yield *sujee muttee* or native carbonate of soda?⁴ Is nitrate of soda never found in this soil, either when it is calcareous or when not calcareous? What is the source of the carbonate of soda itself? Could a solution of potassa or soda be substituted for milk of lime in Collard de Martigny's experiments with equal success?

With these queries I conclude, hoping to call the attention of those interested in developing the resources of India to these points, which are not only of scientific interest, but also (I think) of no little practical utility.—*Transactions of the Medical and Physical Society of Bombay.*

On the Chemical Composition of Steel.

DR. CRACE CALVERT read a short paper on this subject at the meeting of the British Association. He said it was only of late that chemists had attempted to investigate the composition of steel, though it was one of the highest importance to manufacturers. Science, however, had not rendered the service that was anticipated. The nature and properties of steel were so different to iron, that chemists had not progressed in regard to its composition as might have been expected. There was a very warm discussion going on now between chemists on the

Continent, one party contending that nitrogen was an essential agent in converting iron into steel, and the other party that nitrogen was not at all necessary, and that carbon was alone essential. He (Professor Calvert) had made one observation which he thought would interest the chemists assembled in Manchester. For the last two or three years he had devoted considerable attention to the carbon existing in cast iron. In treating cast iron with a weak acid he had succeeded in removing 75 per cent. of the metal, leaving a light graphitic mass, composed of silicium, carbon, and nitrogen. What was exceedingly interesting was that this cast iron contained 1 per cent. of nitrogen, a body which chemists did not actually know existed in it, though its presence was suspected. It occurred to him that if a weak acid enabled him to get at this carbon in cast iron, it would be interesting to see what carbon there was in steel, and possibly he might come to the point in discussion amongst the Continental chemists. In making his experiments he came to this interesting fact, that the different properties which steel acquired by tempering was not a mere molecular change, but a complete chemical change took place during the moment. He took two pieces of the same steel, one soft and the other hardened. Both were placed at the same time in weak acetic acid. The hard steel now was nearly dissolved, whilst the soft steel remained nearly in the same state as when put in. The hard steel was covered with carbon, having the appearance of lamp-black; whilst on the soft steel the carburet of iron was perfectly grey, and was composed of carbon, iron, and perhaps nitrogen. He hoped, with future experiments, to be able to throw more light on this subject.

On the Estimation of Nitrogen, and on an Acidimetric Process, by M. CAREY LEA.

IN a late number of the CHEMICAL NEWS a modification of Will and Varrentrapp's process for the estimation of nitrogen is proposed by Mr. J. Walker. He decomposes the substance in a combustion tube in the ordinary way, but instead of conducting the products of the combustion into chlorhydric acid, conducts them into solution of chloride of zinc, and in place of determining the ammonia in the usual manner, determines the amount of oxide of zinc precipitated by it. "This process," the author observes, "has been practised by me for the last two years, and gives most accurate results, and I can with perfect confidence recommend it."

Few chemists would be apt to adopt a process so obviously worthless, but as its author recommends it especially for the analysis of manures, and as in that way it might be employed for technical purposes, it seems desirable that its gross inaccuracy should be pointed out. Oxide of zinc is well known to be easily soluble in ammonia salts; if a drop of caustic ammonia is let to fall into a solution of pure neutral chloride of zinc, it occasions a precipitate of oxide; if now solution of sal-ammoniac be added, the precipitate redissolves. Obviously, if more ammonia instead of sal-ammoniac is added, sal-ammoniac is formed by the decomposition of the zinc salt, and a portion of the precipitate is redissolved by it, or, to speak more correctly, a portion of the oxide of zinc which is liberated by the ammonia is held in solution by the sal-ammoniac. The necessary result must be an under-estimation of the ammonia, leading to

³ "I have not been able to ascertain whether the *sujee muttee* (native carbonate of soda) is found in this district; as far as my own observations have extended, it does not form a part of the composition of the soil. I also could not detect any alumina, though it is likely some parts may contain it."

⁴ In the Madras Presidency limestone does accompany the native carbonate of soda.—"A thick bed of lime frequently occurs at the depth of six or eight feet from the surface, covered by the dhoby's earth. The natives appear to be aware of this, and frequently dig in such localities in search of lime."—Hunter's "Indian Journal of Arts," &c., i. 432.

errors of such magnitude as would render the process wholly unfit even for the roughest technical process.

In consequence of overlooking the frequent solubility in alkaline solutions of certain metallic oxides and basic salts insoluble in water, even chemists of experience have been led into singular errors. Dr. Friedrich Mohr, in his interesting book on "Volumetric Analysis," highly recommends a process proposed by Kieffer for acidimetric estimation, and which is briefly as follows:—Sulphate of copper in solution is treated with liquid ammonia until the precipitate formed is nearly re-dissolved; it is then filtered, diluted to a certain strength, and constitutes the test liquid. If this be dropped into an acid, or an acid solution, after the addition of a certain quantity a precipitate falls, the appearance of which Kieffer and Dr. Mohr consider to mark the moment of the exact saturation of the acid liquid by the joint action of the ammonia and copper. Dr. Mohr observes:—

"Il n'est le moindre excès de la liqueur de dosage formera un précipité bien net, tout à fait insoluble dans la dissolution des deux sels complètement neutres."²

Here is an important error, this precipitate is by no means insoluble in such solutions, it is soluble with considerable facility in solution of sulphate of ammonia (in the above passage Dr. Mohr refers more particularly to the dosing of sulphuric acid), and also, though to, perhaps, not so great an extent, in solution of sal-ammoniac and of nitrate of ammonia. Consequently, when the precipitate appears, it is because the solution is saturated with it. If it were not that the effect of the cupro-ammoniacal solution is directed to be determined empirically and not by calculation, this solubility would have led to discrepancies no doubt sufficiently great to have awakened suspicion. But the error is just sufficiently great to make the process dangerous. More or less of the precipitate is held in solution according as the saline solution is more or less dilute. Consequently, if the liquid to be analysed contains no saline matter, the error may be but trifling, the error in the analysis correcting more or less accurately the original error in the determination of the "titre." This mode of estimation is particularly recommended for determining the quantity of free acid in acid saline solutions; but here is just where it would be most fallible, the nature and quantity of the saline substance in solution exerting a powerful influence on the solubility of the precipitate. It is evident that a solution containing five grammes of free sulphuric acid with five grammes of sulphate of ammonia, tested in this way, would give quite a different result from one in which five grammes of free acid was contained with twenty or fifty of sulphate of ammonia. Likewise its results when used in the "method of residues" must be false. Accordingly, in an experimental trial by Dr. Mohr³ for the determination of magnesia by supersaturation, with a known quantity of sulphuric acid, and determination of the residue of uncombined acid, the result which he obtained is erroneous by four per cent. Four per cent. too little of magnesia were obtained, because the free sulphuric acid was over-estimated, the ammonio-cupric solution having been added till a precipitate was obtained, which, as we have just seen, does not fall till after the saturation point has been reached.

The precipitate which appears in all these cases is

spoken of by Dr. Mohr as hydrated oxide of copper. It appears to be basic (probably quadribasic) sulphate.

In making these observations on a single process of Dr. Mohr, I wish, at the same time, to bear testimony as to the candour with which he has given the results of his experimental trials. The proposal of a mode of analysis such as that of Mr. Walker is a new proof how much it is to be regretted that any chemist should offer a new mode of analysis without having first controlled it by the analysis of one or more specimens of substance of a known composition. In this way MM. Glénard and Guillemond have recently proposed⁴ a method of estimating the quinine in barks. It has been, however, shown,⁵ that not only the presence of cinchonine destroyed the accuracy of these results, but that, owing to a mistake of the authors as to the reaction of the sulphates of quinine upon tincture of logwood, the process when performed with pure quinine gave only one-half the true result.

In connection with the foregoing observations on zinc I may remark, that an error has crept into the description of zinc reactions in Gmelin's "Handbook." It is there stated that zinc salts give precipitates with ferrocyanide and ferridcyanide of potassium, both of which are soluble in chlorhydric acid.⁶ As respects the precipitate with ferrocyanide, this is certainly erroneous, the precipitate does not redissolve in that acid.—*American Journal of Science.*

On some New Aniline Colours,

by W. CROSSLEY, Analytical Chemist, Middlesborough.

If aniline be mixed with bisulphide of carbon, and allowed to stand for some days, sulphuretted hydrogen is evolved and a cream-coloured, fatty-looking body left. If a little fuming nitric acid be carefully added to this, a beautiful crimson-coloured substance, along with a dirty-brown body, will be produced. I have found no good method for separating the two. But if a portion is first dissolved by boiling in alcohol, and then fuming nitric acid carefully added, drop by drop, a crimson-coloured fluid is produced, which dyes either woollen, silk, or cotton, although they take it more readily if it be first slightly acidified with sulphuric acid. Again, by dissolving the above-mentioned fatty substance in benzole and treating with nitric acid, a fluid is produced which may be used for dyeing lemon-colour. I ought to mention that if either the solution in alcohol or benzole be allowed to cool before the nitric acid is added, a large quantity of clear crystals will separate.

None of the above colours rival, or even equal, those already known, but the reactions are interesting, and I think them worthy that attention which I, from press of other business, am unable to give.

Chemical Prize.—A Gold Medal, worth 600 francs (23l. 16s.), is offered by the Utrecht Society of Sciences, for a memoir on *The Rigorous Determination of the Atomic Weight of at least 100 Elements among those on which M. Stas has not yet published Researches.* The memoir must be sent before November 30, 1862, to Dr. J. W. Gunning, the Secretary of the Society, Utrecht.

TECHNICAL CHEMISTRY.

Notes on the Naphthaline Colours, by CHARLES B. C. TICHBORNE.

As the investigations of M. Z. Roussin are now attracting some attention, I may be excused for mentioning some peculiarities observed by myself during a repetition of his experiments, particularly as there has been very little published as yet regarding the manipulatory minutiae. Presuming, therefore, that the readers are already acquainted with the general *modus operandi* of his "artificial alizarine" experiments, I wish to point out some few difficulties which strike me on looking back at a *resumé* of my working, the overcoming of which are imperatively necessary to ensure success.

M. Roussin directs the binitronaphthaline and sulphuric acid to be mixed together, and then to be heated to 392° F. Now, as this is a great temperature, and generally requires some time to raise it to the requisite point when operating on a large scale, I think it preferable to heat the sulphuric acid nearly to 400° F. before adding the naphthalic compound, by which means a considerable loss of the latter substance is avoided. If this plan be not adopted, the temperature should be raised as quickly as possible to 392° F., but, as will be shown, on no account should the reducing agent be added until that point be reached. In the original memoir we are told to add the reducing bodies in successive portions, at a time when the menstruum has arrived at 392° F.; upon proper attention to this part of the process the entire success of the operation depends. The colouring matter is, in a measure, slowly formed at a lower temperature than that specified, so that on adding a quantity of the reducing agent it will under such circumstances produce a considerable amount; but from the chemical action sufficient heat is invariably generated after some time to bring it much above the stipulated point; when such is the case, a violent action sets in which is completely beyond control.

When the mixture is at 400° F., and not before, it should be taken off the heating medium, and the reducing agent in a state of fine division added in small proportions at a time, the whole being constantly stirred. A little heat may be again employed if the thermometer seems inclined to fall. By attention to these injunctions the action sets in at once on the first addition, and proceeds in a quiet and uniform manner; the heat generated (although being expended in a great measure) is generally sufficient to keep up the temperature.

The question was mooted at one of the late meetings of the British Association at Manchester, whether colouring matters could be procured from naphthaline at all, and whether such matters were not aniline products produced from the use of an impure hydro-carbon; and I believe, although I had not the pleasure of attending those meetings, that the statement was made that the colours could not be made from pure naphthaline. That this is a mistake is evident from the composition of M. Roussin's so-called alizarine, and because I have succeeded equally well with the chemically pure naphthaline. To procure this compound I took the ordinary article and re-crystallised it from an alcoholic solution acidulated with acetic acid. These crystals, on being re-dissolved in alcohol, were precipitated with distilled water and thoroughly washed. When boiled with acidulated water, which was afterwards concentrated and tested, it was found perfectly free from aniline.

When dry I projected it, a small portion at a time, into 4 times its weight of pure nitric acid (specific gravity 1.500); this gave about 1½ part of pure binitronaphthaline. The mother liquors which first drained from the crystals gave a precipitate on dilution with water, which, however, seemed to contain other compounds. On the further treatment with sulphuric acid and tin, the so-called artificial alizarine was procured in considerable quantities. The direct extraction of this colouring substance may be brought about in the following simple manner:—After boiling some minutes with water, it should be as nearly neutralised as possible with a solution of potash, and the resulting precipitate thrown upon a calico filter; as soon as it is thoroughly drained, the dye may be extracted from the black mass by hot methylated spirit, to the amount of about 60 to 70 per cent.

M. Dumas, in bringing M. Roussin's communication before the French Academy, said, that as the author had not at present given an analysis of the new product, its identity with alizarine was not yet proved, and I am not aware that one has been since published. I cannot myself supply the void, at present I have not succeeded in isolating it in a sufficient state of purity for analysis, but I have no hesitation in saying that it is destitute of nitrogen, and therefore can have no connection with any of the aniline colours. *Vide* the different analyses of those substances already published.¹ This can be proved by taking a solution of the colouring matter in potash, and evaporating to dryness on a water-bath to expel the least trace of ammonia, and then testing by Lassaigne's method—*id est*, by fusing with potassium, &c. The result is—no indication of the presence of nitrogen. But when this experiment is tried, and a small quantity of mauve or fuchsine added, the presence of Prussian blue is immediately exhibited.

I found that when binitronaphthaline was intimately mixed with *Hepar sulphuris*, and the mass slightly moistened with water, the whole of the naphthalic substance was converted into a most brilliant colour on the application of heat; but on going the following morning to examine this apparently cheap and easy method of procuring a splendid dye, I found my bird had flown, and the colour entirely faded.

On further investigation I found that this was due to the presence of the alkaline hyposulphite,—the hyposulphites instantly bleaching the naphthaline colours; but by subjecting the *Hepar sulphuris* to great heat, and so converting it entirely into penta-sulphides and sulphate, the difficulty is nearly overcome; and I have great hopes that this process may be practically turned to account. But the purest red, I got in an experiment in which I tried the direct reducing action of protoxide of iron upon binitronaphthaline,—*id est*, by treating the latter substance with proto-sulphate of iron and an excess of potash.

As M. Roussin states, a blue colour is easily procured by the action of cyanide of potassium upon binitronaphthaline, but it is not a very pure blue, and presents a slight greenish shade. This substance dyes a brilliant green on the addition of a small quantity of dinitraniline. Dinitraniline acid and the other yellow tar products are not applicable.

There have been few technical discoveries within the last few years which have created so much excitement amongst the *savants* and the public at large as the aniline dyes, not only from the scientific interest attached

¹ Béchamp's fuchsine $C_{12}H_{11}N_2O$. Phenamine (the name given to aniline violet by Scheurer-Kestner) $C_{10}H_{14}N_2O_2$.

to such disclosures, but also, as the President of the British Association intimated in his inaugural speech this year, because no doubt, in time to come, instead of being dependent upon other countries for our supply of dyeing materials, we should become an exporting nation to supply the wants of other kingdoms,² the advantages being, not only independence of foreign importation, but the opening of entirely new branches of trade, in which branches our old acquaintance King Coal is still our friend, and gives us preeminent standing in working this new mine of wealth.

If aniline opened such a field before us, how much more bright must be the prospect that the naphthalic colours present. The price of aniline being still very high, in spite of all the attention devoted to its cheap production. Nor is there the least probability of a cheaper result. But here is naphthaline, at one time the curse of the tar distillers, become an article of vast importance, although formerly it was frequently the case that they were compelled to bury this unprofitable acquaintance.

Laboratory, Apothecaries' Hall of Ireland.

PHARMACY, TOXICOLOGY, &c.

On the Active Principle of Cornus Florida,
by JOHN M. MAISCHE.

No complete analysis has as yet been made of the barks of the various species of *cornus*. In Vol. vii. p. 109, of the *American Journal of Pharmacy*, Mr. James Cockburn details the results of a number of experiments made with the bark of *cornus Florida*, which are not without interest, but leave us in the dark about the nature of the true active principle of this indigenous tree. This is ascribed by him and by other investigators to "bitter extractive," a name which has to cover a multitude of compounds, difficult to isolate.

In compliance with the subject accepted by me for investigation for the American Pharmaceutical Association, I have directed my efforts principally to the isolation of the active part of this bark, without taking much notice of the other principles it contains; but it was necessary first to obtain some information about these other constituents.

I have therefore repeated and variously modified some of the experiments made by Mr. Cockburn, and find them mainly correct; I was unable, however, to obtain the crystalline substance of which he speaks, and for which I did not search any farther, as these crystals are stated to be entirely tasteless, and my main object lay in a wholly different direction.

Alcohol and water both extract completely the bitter taste of the bark of *cornus florida*, leaving a tasteless residue which imparts no taste to a diluted acid. It is therefore unnecessary, for the extraction of the bitter principle, to contaminate the exhausting liquid with a foreign acid, which would serve no other purpose except to require to be removed again. By extracting the bark with alcohol, the tannin, resin, some waxy matter, free acid, &c., are taken up and interfere with the purification of the extract. Water dissolves no resin, wax, or fatty matter, but on the other hand takes up some gum which may be easily got rid of. Alcohol and water dissolve the whole of the colouring matter.

The neutralisation of the free acid, contained in the

infusion and tincture, does not visibly affect the appearance of the liquid; an excess of alkali deepens the colour somewhat, without otherwise disturbing it; alkalies cause no precipitate of the bitter principle. It was to be inferred, inasmuch as most alkalies are but sparingly soluble in water, that the bitter principle was not of an alkaline nature. If it is of neutral behaviour, the aim, it appeared, must be to remove the other substances so as to retain the bitter active body in solution; or else, take it up by a solvent, which leaves the other bodies behind.

Without attempting to enter into detail on the various experiments made for this purpose, I may as well state the result of my investigations, giving some explanations afterwards.

I have succeeded in obtaining the bitter principle of the bark of *cornus florida* in a perfectly colourless and neutral solution; but all attempts to evaporate the liquid without decomposition have signally failed. No matter whether the alcohol or the aqueous colourless solution is evaporated by rapid boiling, at a moderate heat, at ordinary temperature, in a current of dry air or over sulphuric acid under a bell glass, in all cases a brownish colour is produced, which is deepened as the liquor is concentrated, and a dark brown extract is left behind without the least sign of crystallization.

This colourless solution of the active principle may be obtained in various ways; I have found the following to be the least troublesome:—

Coarsely powdered dogwood bark is twice boiled with water, and the expressed clear liquid is precipitated by solution of subacetate of lead; a flesh-coloured curdy precipitate takes place, which, on stirring becomes very voluminous, and now contains the tannic and gallic acids, gum, colouring matter, &c. The liquid, which is filtered off from the precipitate, is destitute of colour, and contains the bitter principle, together with free acetic acid, and an excess of the precipitant. The excess of lead may be removed in various ways, either by a little sulphuric acid, or by sulphuretted hydrogen; if sulphuret of ammonia, or an alkaline carbonate is used, the alkali serves to neutralise the free acid; the former precipitants require the subsequent use of an alkali to saturate the acid.

Now, in whichever way the lead has been removed and the acid neutralised, the solution remains colourless and neutral for some time at ordinary temperature; but if it continues in contact with the air, and is allowed to evaporate, a decomposition takes place and an extract remains behind, which is still of a neutral reaction, if for the neutralisation of the free acetic acid a fixed alkali has been employed; if, however, ammonia has been used, the extract will have a slight acid reaction from the formation of the acid acetate of ammonia, and the expulsion of some of this volatile base. When evaporated to a syrupy consistence, and now mixed with strong alcohol, the whole liquid is redissolved, with the exception of a white crystalline precipitate of alkaline acetates, and sulphates. All the colouring matter goes into solution, and on evaporation a bitter extractive mass remains, which is wholly soluble in water and alcohol. Its solution is again precipitated and decolorised by subacetate of lead, and the filtrate has now the same behaviour as in the first instance.

By digesting the decoction with carbonate of lead, litharge, or hydrated oxide of lead, the tannic acid of the dogwood bark is precipitated, but at the same time the liquid is rendered turbid by keeping some lead in suspension, which is not removed by filtration; as it

² "It is more than probable that England, instead of drawing her dye stuffs from foreign countries, may herself become the centre from which all the world will be supplied."—*Mr. Fairbairn's Speech*.

passes the filter the liquid is still turbid, and to render it clear, requires to be treated with sulphuric acid or sulphuretted hydrogen, in order to precipitate the lead, which at the same time throws down a considerable amount of colouring matter, but leaves the filtrate still with a decidedly brown colour, which cannot be removed in this way.

A similar result is obtained if the removal of the tannin is attempted by precipitating it with gelatine; the whole amount is not very readily thrown down, and the filtrate has retained a good part of its colouring matter.

More completely than by the latter two ways will the decoction be decolorised by first dissolving in it some alum, and precipitating it again by one of the alkalies, or their carbonates. The alumina which precipitates, will also carry down all colouring matter and tannin, so as to yield a clear colourless filtrate, which, besides the excess of the saline additions, contains the whole of the bitter principle. If this solution is now evaporated, the same change takes place with the organic matter; it turns dark; from the syrupy residue, the saline admixtures are thrown down by strong alcohol, but the colouring matter is dissolved, and, on evaporation, a bitter extract is left behind, without any traces of crystals. The extract, dissolved in water, and treated with alum and an alkali as before mentioned, again yields an almost colourless solution, which shows the same behaviour as before.

In the above experiments, after the bitter principle had been repeatedly deodorised and evaporated, the precipitates of lead or alumina would not carry down the whole of the colouring matter, but leave the filtrate of a yellowish colour, which grew deeper with a repetition of the experiment; the bitter taste of the resulting tincture and extract was now perceptibly less marked, and had nearly entirely disappeared in two specimens of extract, which had been thus treated, and afterwards kept for six months exposed to the air.

I have mentioned above in which various ways I attempted to evaporate the clear solution, so as to prevent change, and it is unnecessary to dwell more upon this matter, as the result has been nearly the same, the chief difference being a somewhat higher or less degree of colour.

A number of experiments were undertaken with the view of obtaining a precipitate from the colourless solution, which should contain the bitter principle; but all attempts have so far been fruitless. It was thought that an ethereal solution might be less likely to become coloured, as its evaporation might be carried on at a very low temperature, and the ether itself would act as a deoxidizer. But no such solution could be effected; ether would not take up the bitter principle from water or alcohol, nor would it cause its precipitation from the spirituous solution.

The presence of free alkalies or acids, during evaporation, appears to hasten the change of the bitter principle; the solution resumes a colour of a marked deeper tint, and the peculiar odour exhaled from a decoction of dogwood bark, seems to be stronger.

If I may be justified to deduce any inferences from the results of the experiments as stated above, they would be as follows:—

The bitter principle of the bark of *cornus Florida* is a colourless, neuter, persistently bitter substance, which is very soluble in water and alcohol, insoluble in ether, not precipitated by chemical re-agents, but very easily affected and destroyed by exposure to the air.

This at the same time furnishes an answer to the other question propounded to me; my inability to obtain the active principle in a pure state rendered a comparison with quinia impossible.

My experiments imply some useful hints regarding the mode of making pharmaceutical preparations of dogwood bark. Contact with the air and exposure to heat, it would appear, must be avoided; a solid extract is best evaporated in vacuo; in preparing a fluid extract, the liquid ought to be brought under the protective influence of sugar as soon as possible. For such preparations, water is a better exhausting menstruum than alcohol, which would take up inert resinous matter; this, in its pure state, is almost white, crummy, soluble in alcohol and ether, also, in alkalies; destroyed upon platina foil without fusion, leaving much charcoal; it is tasteless, and apparently without influence on the human body.

Although having failed so far in my attempts to isolate the bitter principle of *cornus florida* in a crystalline state, I intend to institute further researches upon this subject, the results of which I may probably lay before the Association, if they should prove to be new and more satisfactory. The isolated principle will, no doubt, be interesting, but, I suppose, of little practical value, if we are to judge by the above properties.

I may remark yet, that I have also somewhat experimented with the bark of *cornus sericea*, but with no better result.

PHYSICAL SCIENCE.

How to make a Gyroscope.

A simple Gyroscope may readily be made from a "patent metal top." Fig. 1 represents a section of one of these

latter: it consists of a heavy wheel, C D, revolving round a rod, A A', and kept in its place by projecting pieces of metal, B B'. Motion is given to C D by rapidly unwinding string from D, and if the top be now placed on the ground, the revolution of C D carries round the rod A A', and a continuous spinning ensues.

In order to make a gyroscope from such a top, we divide A A' at E (Fig. 1); a piece of copper wire, about one-sixth of an inch in diameter, is next formed into a circle, G G' (Fig. 2), the diameter of which is equal to the distance between the opposite ends A' and E, which are soldered into it. At the point where A' touches G G', a small piece of sheet copper, F, is fixed; to this a double swivel (such as is used for pike fishing) is attached by means of a piece of string passing through the hole H.

When C D is in rapid motion, the swivel is suspended from a piece of stout wire, and becomes a centre round which the whole may revolve.

This gyroscope costs about 2s.; it works well, although, as far as appearance is concerned, it will not bear comparison with its more elegant brethren, which can boast a finely-turned copper wheel, with a steel axis smoothly revolving in a brass ring.

NOTICES OF BOOKS.

Report of the Committee on the Decay of the Stone of the New Palace at Westminster.

SECOND NOTICE.

IN continuation of the reports which have already been presented *in extenso* to the notice of our readers, we purpose now to enter upon a critical examination of the several projects which have been submitted for the consideration of the "Decay of Stone Committee." Many of the propositions appear to have been at once rejected, on the ground of their being altogether inapplicable to the wants of the case; in other instances the proposals could not be entertained on account of the over-anxiety displayed on the part of the inventors, lest they should betray the secret of their composition, or by objecting to the announcement of the data upon which alone a sound judgment could be based. Thus it happens that among the great number of processes suggested, only a dozen or so appear, up to the present time, to have been selected for further examination; and even these few enumerate more than one example in which the efficacy of the mode of treatment will have to be determined solely by the inspection of treated surfaces, and without the assistance likely to be derived from a full knowledge of the chemical properties of the materials actually employed.

The witness first examined by the Committee was Mr. Nicholas Charles Szerelmey, who has gained for himself some celebrity by the successful manner in which he has hitherto preserved his secret, and who still declines to communicate any more than the barest information respecting the nature of the process employed by him in coating certain external portions of the Palace at Westminster, which, from their early showing signs of decay, were put under the treatment of Mr. Szerelmey as far back as the spring of 1857. The evidence elicited during this gentleman's examination is of the most conflicting character; at one time it is affirmed that no oily nor bituminous matters had been used in the preparation of the stone, but shortly afterwards the employment of Egyptian asphaltum, from the Dead Sea, is distinctly admitted, and, as a solvent for the same, some kind of mineral oil. With regard also to oxide of zinc, Mr. Szerelmey denies that his composition contains this material, but the report of the chemists on the Committee, addressed to their Chairman, refers particularly to the presence of oxide of zinc as a constituent of the preparation applied to the Spenker's doorway. This appears, however, to have been a special ingredient used at a time when Sir Charles Barry made the suggestion to try the effect of colouring matters in conjunction with the witness's ordinary preparation.

The use of a soluble silicate as a first application forms apparently the groundwork of Mr. Szerelmey's process, and the varnish made from Egyptian asphaltum, subsequently applied, is intended to protect the silicate in the pores of the stone from the action of the atmosphere and external influences generally. Three coatings are referred to as being necessary for the successful manipulation of the process; but it does not appear whether any two of these coatings are identical in character or otherwise.

In looking now to the results of the experiments, it would appear that the four years' interval which has

elapsed since their first application has demonstrated that a considerable degree of protection has been afforded to the stone; and when proper account is taken of the severity of last winter's frost, and the depth to which the stone itself must thereby have been subjected to extreme cold, there is reason to conclude that the effort of Mr. Szerelmey is at least a partial success; but in the event of its being selected among others for further experimental trial, it must surely be necessary to insist upon a candid explanation being afforded in regard to the exact nature of the ingredients actually applied to the surface of the stone.

NOTICES OF PATENTS.

361. *The Suppression of Arsenical and Sulphurous Fumes emitted during the First Operation or Calcination of Copper Ores.* E. T. JONES, Morden College, Blackheath. Dated February 13, 1861. (Not proceeded with.)

THIS invention has for its object the condensation and recovery of the arsenic and sulphur products which are given off in great abundance during the operation of roasting copper pyrites, and similar ores of that metal. The improved arrangement of apparatus consists, firstly, in the employment of large iron or clay retorts, such as are used in the manufacture of coal gas, in which retorts the roasting operation is carried on, and the volatile products escaping from the heated ore are led forward into a second or condensing arrangement, which consists of a long iron tube, about twenty feet in length, and from six to eight inches in diameter, the further end of which is made to dip just beneath the surface of water contained in a box or receptacle measuring four feet in every direction. For the effectual cooling of this part of the apparatus, a constant flow of water must be maintained in an outer cistern, within which the condenser is totally immersed; or, instead of this form of refrigerator, a one-inch leaden pipe, perforated on the lower side with small holes, and made to deliver freely a supply of cold water, may be fastened along the upper surface of the iron condensing tube. The appliances for clearing the tubes of the arsenical deposit, for receiving the heated charge from the retorts when sufficiently calcined, and other particulars relating to the mechanical arrangement, are described in the specification.

Anyone who has personally visited the copper-smelting district of Swansea, and noticed the desolation conferred upon the immediate neighbourhood by the volumes of copper smoke pouring forth night and day into the atmosphere, cannot fail to appreciate the value of any practical suggestion which will have a tendency to diminish the evil complained of, and if to this consideration be superadded the equally important question of economy, the subject becomes certainly worthy of renewed investigation in the hope of discovering really efficient means of satisfying the wants of the case. The process long since patented and worked by Mr. William Longmaid, for converting the sulphur of iron and copper ores into sulphate of soda, as a stage in the alkali manufacture, was a great effort in the right direction, but has not, so far as we are aware, met with general adoption in the case of the richer ores of copper. The method of proceeding referred to in the specification above, does not appear to take sufficiently into account the necessity for establishing a powerful current of air through the roasting furnace, in order to facilitate the oxidation and expulsion of the sulphur from the ore.

376. *Manufacture of White Lead, Zinc White, and Glazier's or Potter's Lead.* T. COBLEY, Dated February 14, 1861. (Not proceeded with.)

For the purpose of communicating increased density,

greater permanence of colour, and drying properties to white lead and zinc-white pigments, the inventor proposes to subject them to the action of a solution of borax or other compound of boracic acid. Potter's glaze is by the same means rendered more fusible, and metallic lead itself considerably softened by melting with borax.

It would be difficult, we imagine, to increase the density of white lead by the introduction of borax. The use of this substance in connection with pottery is well understood in this country, and always employed whenever the character of the work will warrant its expense.

378. *Impregnating the Atmosphere with Perfuming or Purifying Vapours.* R. RIMMEL, Strand, London. Dated February 14, 1861.

The patentee claims the vaporisation or volatilisation of perfumes by mixing them with an aqueous base and obtaining the disengagement of the fragrant molecules by means of heat or steam. He also claims the disinfection of the atmosphere, and of all bodies, by means of aromatic vapours.

In reference to the means of disinfection here referred to there is a danger of assuming that the introduction of pungent aromatic vapours must necessarily counteract as they disguise the element of contagion present in a vitiated atmosphere. There is no doubt that camphor, vinegar, and other substances are really efficacious when properly applied, but such remedies do not, like chlorine, strike at the root of the evil by exerting upon the dangerous effluvia nothing short of a power of destruction.

383. *Cure and Prevention of Toothache.* M. A. PRENSLAN, Liverpool. Dated February 15, 1861.

For the relief and cure of toothache the patentee uses "oil of paper" which he administers to the cavity of the tooth either by itself or upon cotton wool as a vehicle. The preparation is procured by submitting to destructive distillation in a close vessel any kind of paper made from a vegetable fibre.

This curiosity, "oil of paper," may perhaps owe any efficacy it possesses to the creasote among other tarry products resulting from its mode of formation. If the tuft of cotton wool were itself half consumed by fire before the remaining portion be applied to the tooth, perhaps equally beneficial results might follow; or would it not be better to burn it in the tooth itself?

CORRESPONDENCE.

The Phosphorescence of Decaying Organic Matter.

To the Editor of the CHEMICAL NEWS.

SIR,—It may prove a subject of interest to some of your subscribers, particularly to those residing in the rural districts, to know that at this period of the year some very remarkable phenomena of the phosphorescence of decaying organic matter are to be observed. A great deal has been written, and many explanations given, on the *Medusa* and other phosphoric insects. It is also a well-known fact that many kinds of fish are phosphorescent even a few hours after they have been taken, and also that this does not apparently render them at all unfit for food, although perhaps it is the commencement of that stage when those chemical agencies which exerted all their powers to keep the body in a state of vital existence are devoted to the contrary work of decomposition.

On returning home a few evenings ago, my path lay through a wood of some ten acres in area. The sky was clouded, no moon visible, and the darkness intense. The surface of the ground presented a peculiar aspect. As far as the eye could pierce through the brushwood, a mass of vivid light covered the soil. There were no exhalations of phosphuretted hydrogen, as observed in marshy districts; but as I became accustomed to the change, I appeared to be walking over a carpet of glowworms. I accordingly stopped to examine the cause of the phenomenon; and, on stooping down, gathered several of the phosphorescent bodies which were moist and clammy; having the appearance of frosted silver, and apparently translucent throughout. On arrival at home, I transferred the materials I had collected, and which consisted of half-decayed oak and other leaves, pieces of dead grass, rotting wood and other organic matter in the first stages of decomposition, into a tray, and placed them in a dark room, when all the former phenomena became soon apparent as before. The light evolved enabled me to read printed matter when held close to the luminous bodies. After the leaves, &c., had been dried they ceased to be phosphorescent, nor did they become so on being moistened afresh with water; yet on being kept moist and exposed to the rays of the sun, they appeared to have regained their luminous properties by the next evening. During the rainless days of harvest, when no surface moisture was perceptible, the phenomena were not to be observed.—I am, &c.

Lux.

MISCELLANEOUS.

Disinfection of Sewage.—The Medical Inspector to the Westminster Burial Board, Mr. P. H. Holland, has on a recent occasion described the important results which have followed the adoption of Mr. Macdougall's process

for the deodorization of sewage. The plan has been put into operation in connexion with the town-drainage systems of Carlisle and Exeter, and is stated to have been completely successful both as regards the mitigation of a nuisance and the economical recovery of valuable manuring agents for agricultural employment. The process consists merely in the addition to the sewage of one gallon per diem of crude carbolic acid, costing, with carriage included, only 10s. a day—i.e. £16l. a year,—a sum extremely small as compared with that about to have been spent by the Boards of Health in these towns respectively for the purpose of conveying to a distance that which has hitherto proved a nuisance to the inhabitants and been subject to indictment. The apparatus for conducting the mixing process is as simple as could be desired, and the small proportion in which the disinfectant need be employed renders its application extremely economical.

The Canadian Oil Region.—A Correspondent of the *Toronto Leader* communicates some interesting particulars relative to the important discoveries of mineral oil, which have, in the course of a few months, proved a substantial source of wealth to those engaged, and opened out vast commercial relations in favour of a district which, until very recently, appears to have escaped special notice. The territory of Black Creek derives its name from a creek so-called running through the oil region. It is about half way between the eastern and western limits of Enniskillen township, distant twelve miles from Wyoming, and twenty-four from Sarnia. As we approach the Wyoming station of the Great Western Railway, the peculiar odour of the oil, which is here stored in large quantities for transmission to the eastern markets, is perceived at the distance of a mile or two if the wind happens to be favourable. At a distance of about five miles from Wyoming are the wells known as "Kelly's Wells." They are about a dozen in number, are yielding tolerably, and at one time attracted considerable attention. A refinery has been built at a cost of about 10,000 dollars, and is just now commencing operations. Arrived at the end of my journey, I found the oil region extending over a limited space. From the tests already made, the oilmen have concluded that it does not extend all over the township, as some at first supposed. Black Creek seems to be the richest territory yet discovered in Canada, and, according to some of the best authorities, it is the richest in America. Wandering along the banks and in the flats of the stream, which certainly deserves the name it bears, I at every few rods came across a well. They were in every stage of procedure. Some were just commenced, some were just finished; from many men were pumping oil into huge vats. Here let me say that the wells are of different kinds. First, there are the surface wells, so called because they are only sunk to the rock; these are for the most part on the flats of the creek. Some of them, when within a few feet of the rock, quickly fill with oil, which, with much noise and uproar of gas, bursts in from the loose gravelly substance overlying the rock. I have known wells fifty feet deep and five feet square full to the very brim with oil. Nay, I have seen it flow over the top and run away in a stream, wasting hundreds of barrels. These wells are dug large, the sides are cribbed and then puddled, so as to keep out the surface water. The oil from these wells is thicker and less pure than that from the rock wells, but a refiner told me that, though it was harder to deodorise and refine than the rock oil, yet, when manufactured, it made the best oil; having more body, it gave the best light, and burnt longer. It is also best for lubricating purposes. For rock wells they frequently sink a well like a surface well, and then drill; but more frequently the soil is bored out with a large augur until the rock is reached, a distance varying from forty to seventy feet. Then piping like pump logs is put in and driven down snug on the rock. After this the slow process of drilling is carried on, by foot, horse

power, or with steam engines, sinking from a few inches to perhaps ten feet per day, according to the nature of the rock. The character of the rock seems to vary with every well. It is generally, however, soapstone, with layers of shale, which is here in very small quantities; though at other parts of the township I have known drillers to go through fifty or sixty feet without change. There are also layers of sandstone, flint rock and sulphuret of iron; these vary in quantities at every well, though distant but a few rods. In the soapstone the oil is generally found, and at various distances from the surface. A continuation of little veins may be struck; then all at once a larger one, which may cause the oil to be forced in immense quantities out of the pipe. The quantity of oil this country is capable of producing is amazing. I have seen more oil, and a greater number of wells in operation and in course of being sunk, than I ever imagined as being in this county. I was told that, before January, 500 wells will be down. Large vats and tanks contain the oil, some of them holding as much as 1000 barrels; the largest are immense pits sunk in the stiff clay, cribbed and puddled, and these, they say, are better than wooden vats, which allow the oil to leak out, so penetrating is its nature. While I was there quietly looking on, I saw wells yield day after day from ten to fifty barrels. Estimating the wells in actual operation at 300, this would give 3000 barrels per diem at the lowest rate of production. And this, I assure you, is a small calculation; ten barrels per diem is moderate, and there will be double 300 wells before a year at the present rate of sinking. As far as I could judge, failure is the exception. Not one man in twenty who pretended to be in the oil region, failed to get oil; nor has any rock well shown signs of drying up. There is no doubt that we have at hand a source of untold wealth—an oil territory richer than any yet discovered. And, thanks to the enterprise of the Canadians, one firm in Toronto has undertaken the oil-refining business, while another is exporting it largely to Europe. Once the European market is opened, it must create an immense trade, for a substance from which are made refined toilet soaps, candles superior to wax, oil that gives a cheaper and not less beautiful light than gas, and much more convenient, and furnishing the best machine and lubricating oil yet known, must ultimately be brought into universal use.

ANSWERS TO CORRESPONDENTS.

*. * All Editorial Communications are to be addressed to the Editor; and Advertisements and Business Communications to the Publisher at the Office, 1, Wine Office Court, Fleet Street, London, E.C.

*. * In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

J. A. D.—Declined with thanks.

A. H. B.—1. See the solution for marking on zinc plate, given in our Eighty-fourth Number. 2. It is a difficult process: try distilling. 3. We do not know the work.

Constant Reader.—To precipitate chloride of silver from a composite saline solution when present in the smallest quantities:—Concentrate as much as possible by evaporation, add sulphuretted hydrogen and white of an egg, boil. The albumen in coagulating will carry down the sulphide of silver, which may afterwards be treated by cupellation. Silver can in this manner be detected in sea water.

Red Gauntlet.—1. Allow strong ammonia to digest with metallic copper in fine turnings, with free access of air. 2. For a description of the mode of preparing artificial malachite, see our Second Volume, page 279. 3. We do not think an ether is known which has the odour of rose or patchouli.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Classification of Organic Substances by Series,
by JAMES SCHIEL, of St. Louis.

(Concluded from page 192.)

The acids form quite a number of generic series.

Series of Acids I.

$C_nH_{2n}O_2$ fatty acids $n=1$ to $n=30$.
 $C_nH_{2n}O_3$ glycolic acid $n=2$.
 $C_nH_{2n}O_4$ glyceric acid $n=3$ (isomeric with lactic acid).
...

The acids of this generic series correspond to the first alcoholic series.

Series of Acids II.

$C_nH_{2n-2}O_2$
 $C_nH_{2n-2}O_3$
 $C_nH_{2n-2}O_4$
 $C_nH_{2n-2}O_5$

The special homologous series deriving from this generic series are,

$C_3H_4O_2$ acrylic acid.	$C_2H_2O_3$ glyoxylic acid
$C_4H_6O_2$ crotonic "	$C_3H_4O_4$ pyroracemic acid
$C_5H_8O_2$ angelic "	...
&c. &c.	---
$C_2H_2O_4$ oxalic "	$C_3H_4O_5$ tartronic acid
$C_3H_6O_4$ malonic "	$C_4H_6O_5$ malic "
$C_4H_8O_4$ succinic "	...
$C_5H_{10}O_4$ lipic "	---
&c. &c.	---
$C_4H_6O_6$ tartaric "	$C_6H_{10}O_8$ mucic "
...	---

Series of Acids III.

$C_nH_{2n-4}O_2$
 $C_nH_{2n-4}O_3$
 $C_nH_{2n-4}O_4$
 $C_nH_{2n-4}O_5$
...

From this generic series are derived:—

$C_6H_8O_2$ sorbic acid.	$C_3H_2O_3$ mesoxalic acid.
$C_4H_4O_4$ maleinic acid.	$C_6H_8O_5$ citric acid.
$C_5H_6O_4$ itaconic "	---
$C_6H_8O_4$?	---
$C_7H_{10}O_4$ terebinic "	---

Series of Acids IV.

$C_nH_{2n-6}O_2$
 $C_nH_{2n-6}O_3$
 $C_nH_{2n-6}O_4$
 $C_nH_{2n-6}O_5$

From this generic series we derive:—

$C_6H_8O_2$ oxyphenic acid.	$C_8H_4O_3$ pyromucic acid.
$C_8H_{10}O_2$ terebentic "	$C_6H_8O_3$ pyrogallie "
---	$C_7H_8O_3$ ipecacuanic "
---	$C_8H_{10}O_3$ ricinoleic "

$C_4H_2O_4$ mellitic acid.	$C_6H_8O_5$ aconitic acid. ¹
$C_2H_{10}O_4$ cholesteric "	---

Series of Acids V.

$C_nH_{2n-8}O_2$
 $C_nH_{2n-8}O_3$
 $C_nH_{2n-8}O_4$
 $C_nH_{2n-8}O_5$
...

From this generic series we derive:—

$C_7H_6O_2$ benzoic acid.	$C_8H_8O_5$ krokonie acid.
$C_8H_8O_2$ toluylie "	$C_6H_4O_5$ comenic "
$C_9H_{10}O_2$?	$C_7H_6O_5$ gallic "
$C_{10}H_{12}O_2$ cuminic "	$C_9H_{10}O_5$ cholic "
---	$C_7H_6O_3$ salicilic "
$C_8H_8O_6$ phenoxacetic "	$C_8H_8O_3$ anisic "
---	$C_9H_{10}O_4$ phloretinic "
$C_8H_8O_4$ lecanoric "	$C_9H_{10}O_4$ veratric "

Series of Acids VI.

$C_nH_{2n-10}O_2$
 $C_nH_{2n-10}O_3$
 $C_nH_{2n-10}O_4$
...

Of the acids deriving from this generic series only a few are known as yet.

$C_9H_8O_3$ cumaric acid.	$C_7H_4O_7$ mionic acid.
---------------------------	--------------------------

$C_8H_6O_4$ phtalic acid.
 $C_{24}H_{38}O_4$ choloidic "
 $C_{25}H_{40}O_4$ hyocholic "

From other known acids it is hardly possible to form series, as they stand mostly isolated; there is, for instance, only one acid—anemonic acid $C_{15}H_{14}O_7$ —

¹ The radical of the tribasic aconitic acid $C_6H_3O_3 \left\{ \begin{smallmatrix} H_3 \\ H_3 \end{smallmatrix} \right\} O_3$ may be derived from a hydrocarburet by substitution of H_4 by O_3 , as acetic acid is formed by substitution of H_2 by O in the radical C_2H_5 . The triacid alcohol, or glycerin corresponding to aconitic acid, would therefore be $C_6H_9 \left\{ \begin{smallmatrix} H_3 \\ H_3 \end{smallmatrix} \right\} O_3$; it belongs to the alcoholic series II, answering to the general formula $C_nH_{2n}O_2$, and the type $C_nH_{2n-3} \left\{ \begin{smallmatrix} H_3 \\ H_3 \end{smallmatrix} \right\} O$. This remark applies, *mutatis mutandis*, to other acids.

known as yet, which corresponds with the general formula $\Theta_x H_{2x-1} O_x$.

The generic series of acids considered above may be ranged into one primitive series—

where Θ_x means, that in order to form a generic series from one of these primitive formulas, Θ has successively to receive suffixed the numbers 2, 3, 4, . . . x . It is easy to see that as every generic series, as for instance:

consists of two kinds of series, of which those lying on the horizontal lines are homologous series, and those lying on the vertical lines are series of oxidation, the primitive series therefore expresses a seriation in a cube.

It is worth observing that there may be series of isomeric substances running parallel to each other; such series may be called homarithmical series.

Chemical Researches on the Assay of Silver by the Moist Way, by G. J. MULDER, *Math. Mag. Phil. Nat. Medicinæ, Artis Obstetriciæ et Pharmaceuticæ Doctor, Professor of Chemistry at the University of Utrecht, Grand Cross of the Order of the Netherlands Lion; of the Luxembourg Order of the Couronne de Chêne; of the Swedish Orders of Wasa and Polar Star, &c., &c.*

(Continued from page 139.)

I will even suppose, that when the last drop of nitrate of silver was added, a trace of precipitate made its appearance, but that experience has already taught us that one single drop more added would not have given any further trace of precipitate. Let us first get a nearer insight into this interesting matter; let us then try to explain it, and to answer the question which arises from this fact, and bears upon its technical application, viz.—how to determine exactly the precise quantity of chloride of sodium required to precipitate the quantity of silver originally present in a solution.

It follows from what has been just mentioned, that in the very liquid from which silver had been so precipitated, that the ultimate limit of a perceptible precipitate had been just reached, but nothing more; a decimal solution of silver will in its turn produce a precipitate in such a manner, that to 1002 milligrammes of silver at 15° to 17° C., it would appear as if one had used 0.54141 milligrammes of chloride of sodium too much; and this notwithstanding originally not a single drop of decimal salt solution had been added over and above that, necessary to complete the precipitation of chloride of silver.

The same liquid to which the decimal solution of silver has been just added, so that the utmost limit of precipitation had been reached, can now in its turn again yield a precipitate with the decimal solution of salt; for if this solution of salt be added we shall perceive that again about twenty drops of the solution, the temperature being from 15° to 17° C. will be required in order to reach the limit of another perceptible precipitate. If, on

the other hand, we now again return to the decimal solution of silver, we shall see the repetition of the same phenomena. As long as the chloride of silver keeps white, it is possible to repeat the just-mentioned experiment, and, *vice versa*, we shall find that we can use either the silver or salt solution of identically the same strength in order to reach the limits of a perceptibly visible precipitate, provided also the temperature of the test liquid remains constantly as mentioned.

I have to observe, however, that the precipitate produced by silver is more slowly formed than that produced by salt. It will not be deemed superfluous to enter into more details. It must be observed, that in all the following experiments, unless the contrary be expressly stated, pure chloride of sodium was used for the standard and decimal solution, the standard solution being purposely rendered a little weaker in order to be more fit for use in observing and studying the phenomena to be described now and hereafter. When it is stated that one gramme of silver was weighed off, this is only mentioned in order to make known the quantity operated upon; for in the majority of cases such a solution of salt was used as would require 1003 parts, at a temperature of 15° C., to precipitate 1000 parts of pure silver. It would have been impossible to make the following researches unless I had been provided with such accurate and exact drop apparatus as would enable me to measure the decimal solutions of silver and salt, so that twenty drops of each exactly corresponded to one cubic centimetre. The decimal solutions of salt and silver were chemically an exact equivalent the one towards the other, one drop of the one having the same value as one drop of the other. This also is a chief requisite in order to distinguish what follows.

Pure silver was weighed off in the following quantities:—

- I. 1000 milligrammes.
- II. 1002 "
- III. 1004 "

and each quantity was dissolved in five cubic centimetres of nitric acid of a density of 1.20; it was afterwards precipitated at a temperature of from 15° to 17° C., first with the standard solution of salt, then with the decimal salt solution, until the limit of a perceptibly-visible precipitate had been reached; after this decimal solution of silver was again added, guttatim, two drops at a time, until the limit was reached; then again salt solution and then silver (always the decimal solution of both) solution again, in every instance until the limit was reached.

Decimal Solution of Silver.		Decimal Solution of Salt.

	III. 21		III. 20
E	I. 22	F	I. 22
	II. 22		II. 22
	III. 20		III. 22 ¹

As the average of this experiment, we find that equally large quantities of the equally strong decimal solutions of silver and salt are required to produce a precipitate unto the limits of precipitability. We also find that this limit having been reached, there is a moment when, on applying

¹ The somewhat increased number of drops required when the experiment is continued for some time is due mainly to the heat the bottles receive while being shaken with the hands.

the last but one used precipitant, a new precipitate makes its appearance, which in both cases happens with 21 drops, equal to 1.05 cubic centimètres, or, if expressed in silver, equal to 1.05 milligramme weight thereof.

The experiment just mentioned has been often repeated with pure silver, and has always given similar results. We are, therefore, justified in stating, that, under the very same circumstances, that very liquid which apparently contains exactly enough salt, but no more, yields room for one milligramme of silver to precipitate salt (as chloride of silver of course); while, on the other hand, that liquid which apparently again contains just enough silver has room for 0.54 milligramme of chloride of sodium to precipitate silver.

The question, therefore, presents itself, what may be cause of this? As far as we are aware, the liquid only contains nitrate of soda and free nitric acid and chloride of silver in insoluble condition; nothing else. Chloride of silver may here be deemed as insoluble in water.* A solution of chloride of silver in water cannot be the cause in this instance.

Chloride of silver is soluble in solution of chloride of sodium; but not very much so at the ordinary temperature of the air. 1000 parts of chloride of sodium in concentrated watery solution only dissolve two parts of chloride of silver at 15° C. In case, even, therefore, the liquid in question might, after addition of chloride of sodium, contain a little free chloride of sodium, it would require 500 parts of chloride of sodium to dissolve one part of chloride of silver; but if, moreover, the chloride of sodium were the means of dissolving the chloride of silver, then, instead of a precipitate being generated about the end of the experiment,—a fact which visibly happens,—the formed precipitate ought to be seen disappearing, which is contrary to the effects observed in repeated experiments.

The solvent power of chloride of sodium here spoken of is, in fact, observed; but in order to be perceptible, a large excess of salt must be present, which is not the case in the experiment just alluded to.

Ten cubic centimètres of pure distilled water were mixed with one single drop of the decimal solution of silver, and also one single drop of the decimal solution of salt, a precipitate was formed, which was evidently stronger than a precipitate formed in 10 cubic centimètres of pure distilled water, to which had been added, first, one single drop of the decimal solution of silver, and then 20 drops of the standard solution of salt; in 20 drops of which are contained 5 milligrammes of salt, while one drop of the decimal solution of silver contains 0.05 milligrammes of silver. In this experiment the solvent effect of salt is already visible, but the excess of salt is also very large, for upon 5 parts of silver or 6.7 AgCl, there are 500 parts of salt,—i. e., 1 part of chloride of silver to 75 of salt.

The solubility of chloride of silver in common salt has, therefore, nothing to do with the phenomenon alluded to in the testing for silver. Chloride of silver, moreover, appears to be as much insoluble in dilute nitric acid as in water. To explain this phenomenon, there only remains to be seen whether chloride of silver is soluble in nitrate of soda: in fact, this solubility is the real cause of the mutual precipitation. I shall afterwards have often occasion to show the reality of this fact, but I now only mention the following simple experiment:—

In a bulk of 10 cubic centimètres of a solution of nitrate of soda of unknown degree of concentration, to which a small quantity of nitric acid had been added, 5 drops of a decimal solution of salt, and 5 drops of a decimal solution of silver, yielded a precipitate which on being heated was quite dissolved, whilst on cooling, the precipitate made its appearance again. Chloride of silver, therefore, is soluble in solution of nitrate of soda acidified with nitric acid and heat being applied. But it is not only so on application of heat: it is quite perceptibly so at the ordinary temperature of the room where the experiments take place.³

In order to ascertain whether the phenomenon of the mutual precipitation above alluded to is due to the formation of some double salt, or whether it belongs to the more simple phenomenon of solution, the following experiment was made at a temperature of from 15° to 17° C. Three grammes of pure silver were dissolved in 15 cubic centimètres of nitric acid, and partly precipitated with 300 cubic centimètres of standard solution, after which decimal solution of salt was added. The solution of the 3 grammes of silver was brought to the utmost limit of a perceptible precipitate, but no further. Decimal solution of silver was now added by drops, so as to give the utmost limit of precipitate; thereupon decimal solution of salt was added, and again silver, in every case just unto the utmost limit. The quantity required, therefore, expressed in drops, was the following:—

Silver, 60.
Salt, 60.
Silver, 60.

This experiment with 3 grammes of silver has thus required three times as much decimal solution of salt and silver as the experiment above alluded to. In the former experiment one gramme of silver was the starting point; in this experiment three grammes had been operated upon. Both experiments agree herein, that in either of them a large excess of chloride of silver insoluble in the liquid, is present. The phenomenon in question is, therefore, intimately connected with the quantity of the liquid. This liquid is water, containing nitrate of soda, with a small quantity of nitric acid. In the one instance there are rather more than 100 cubic centimètres; in the other case somewhat above 300 cubic centimètres. There is, therefore, every reason to assume that in order to explain the phenomenon of the doubly mutual precipitation the main cause of this phenomenon is solution, as defined by Berthollet.

It is now time to call attention to another peculiarity. We know already that one gramme of silver precipitated by common salt (standard solution) at a temperature of 15° to 17° C. easily bears 20 drops of decimal solution of silver, and again 20 drops of decimal solution of salt. What will be the condition if only 10 drops of the decimal salt solution are added after the silver solution? And if we refer to the experiment just described, in which three grammes of silver were used, what will happen if after the precipitation with salt to the very limit, instead of 60 drops of decimal silver solution only 30 are added?

Guy Lussac has already alluded to this, although only briefly, for in his "Instruction" he says (page 19):—"Il est à remarquer que, lorsque la dissolution normale

* It is not absolutely so, as has been discussed in this treatise already.

³ I have to observe that when to the last-mentioned liquid had been added 15 drops of the decimal solution of salt, and heat was applied, the precipitate thereby quite disappeared, but reappeared again after cooling. Nitrate of soda and chloride of sodium have, therefore, the property of dissolving chloride of silver with aid of heat.—M.

est parfaitement au titre, elle louchit très légèrement, soit avec le nitrate d'argent, soit avec le sel marin."

Suppose that 10 drops of the decimal silver solution are added to the liquid obtained by dissolving one gramme of silver (temperature 15° to 17° C.) which has been first precipitated with standard solution, and which has been afterwards brought by decimal solution of salt to the very limit; that after the addition of the 10 drops of decimal silver solution, the liquid has been well shaken, and after the precipitate has settled, the clear supernatant liquid be poured off and divided in two test glasses; on addition to the one part of these liquids of nitrate of silver, and to the other chloride of sodium, both in decimal solution, precipitates will be seen making their appearance, which, if the experiment was well executed, will amount to the same quantity in each of the liquids operated upon. I added 30 drops of decimal solution of silver (temperature 15° to 17° C.) to the liquid in which the 3 grammes had been dissolved. After having well shaken the liquid, and after the precipitate had settled, the clear liquid was poured off in two glasses. Five drops of decimal solution of salt having been added to the one, and 5 drops of decimal solution of silver to the other, gave rise in both cases to perfectly similar precipitates.

(To be continued.)

Researches on the Relations existing between Atomic Weights, by M. J. S. STAS, Member of the Royal Academy of Belgium.

(Continued from page 182.)

The Means of Weighing.—Four balances and two sets of weights have served for all my weighings. One of the balances, constructed by the celebrated French mechanician Gambey, carries one kilogramme in each pan, and turns when loaded with this weight to five-tenths of a milligramme. The other three were made by M. Sacré, mechanician to the Museum of Industry at Brussels. The largest of the three, which was constructed expressly for my researches, will bear a weight of five or six kilogrammes in each scale, and marks with certainty under this enormous load a difference of weight of one milligramme. Laden with two or three kilogrammes in each scale, it turns quite perceptibly with a variation of three or four-tenths of a milligramme. The second balance carries five hundred grammes in each scale, and denotes a difference of two-tenths of a milligramme. Lastly, the third, which is an assaying balance, turns definitely when loaded with twenty-five grammes in each side to a thirty-third of a milligramme. I do not believe that there exists another set of balances which for sensibility and accuracy are to be compared with these I have mentioned. Every chemist who has had occasion to examine them has come to the same conclusion; therefore I do not hesitate to say that they do honour to M. Sacré, and I may add that I feel much pleasure in being able to pay this tribute to his ability. The two sets of weights which I used are one of platinum, the other brass. The platinum set contains the kilogramme and all its subdivisions to half-a-milligramme. It was made by M. Gambey, under the superintendence of M. Arago. It constitutes the standard of the second order of the State of Belgium. I had occasion to verify its perfect conformity with the platinum standard preserved in the Chamber of Representatives, likewise made by M. Gambey, and compared by M. Arago with the standard kilogramme deposited with

the archives of the State in Paris. The other set of weights was adjusted by myself with every possible care by means of the platinum standard. The subdivisions of the milligramme down to tenths of these weights are made out of flat silver thread.

Finally, so as to be able to reduce all my weighings to a vacuum, I have determined the specific gravity of platinum and brass. I thus found that the platinum kilogramme displaces 47 cubic centimètres of air, and the brass 125 cubic centimètres. All my calculations have been made from these two data, whether I have performed the weighings in the air and have applied the corrections to both the weights and the material, or whether I have weighed in a vacuum and have submitted to correction the weights alone.

The Weighings.—Whenever the nature of the substance did not offer an insuperable obstacle, I have performed the weighings in air, and have placed as a counter-weight to the vessel containing the substance another vessel of the same nature and size, and, as near as possible, of the same weight as the one which it is intended to counterbalance, the difference between the weights being made up by a further addition of the same material. I have only resorted to weighing *in vacuo* as a means of control or when employing matters which were hygroscopic or liable to absorb air. I have effected the weighings *in vacuo* differently according to the shape of the vessels containing the substances, and according to the nature of the products which were to be formed. When the operation was performed in glass tubes, those containing the materials were introduced in a glass cylinder furnished with a metallic connection and a stop-cock, by which a vacuum could be obtained. To counterbalance this cylinder I employed another, absolutely identical as to its exterior volume, its shape, and matter of which it was composed; besides which, I took all the precautions at first suggested by M. Dumas for effecting in safety a weighing *in vacuo* and always obtaining constant results. When the shape of the vessels would not admit of this mode of operating, I fastened either a metallic connection, by means of a resinous cement, to the mouth of the vessel, or a cap of unvulcanised india-rubber furnished with a stop-cock. In this latter case I took care to use as a means of fastening thick pieces of platinum, silver, or copper wire slightly flattened; and to obviate the action of the air upon the caoutchouc—for in the air caoutchouc absorbs oxygen and increases in weight—I wound the metallic wire round in such close spirals that the surface was entirely covered. An arrangement of this kind perfectly preserves a vacuum, especially if care has been taken to roughen that portion of the glass to which the caoutchouc is applied.

This was equiposed by an apparatus absolutely identical in external volume and extent of surface. This arrangement, suspended in a large frame beneath the balance, hung freely in the air which was kept as dry as possible, and guarded by means of thick wooden partitions from all movements either from currents or heat. MM. Dumas and Regnault have already shown that on weighing with these precautions the equilibrium, once obtained, is preserved indefinitely. Whenever my apparatus has preserved a vacuum perfectly (which is much more difficult to effect than would be supposed) I have been enabled to verify the accuracy of this statement.

In all my weighings *in vacuo* the internal tension was, both before and after the experiment, between $0.0025''$ to $0.003''$; the air-pump would not permit me to go beyond that.

I have already stated above that, unless it was absolutely necessary, I performed the weighings in air; for I have shown in the most certain manner that vessels full of air always have a uniform weight as soon as the surfaces of all those portions of the apparatus which are in equilibrium are under the same conditions. When these conditions are changed, either by a slight elevation or depression of temperature, it takes a long time to bring them to their original state. Thus a tube of hard glass 60 to 80 centimètres long and 2 to 2.5 in diameter, after having been strongly heated, requires to be kept for two or three hours in the balance case before its weight becomes constant. Glass flasks of 1 to 4 litres capacity, after having been heated or rubbed, do not attain a constant weight until they have remained in the balance case for five or six hours.

Polished platinum heated out of contact with flame rapidly regains its primitive weight. But when this metal is more or less roughened it attains its proper weight much more slowly than either glass or porcelain.

The Vessels Employed in the Determination.—I have had recourse to platinum vessels whenever the nature of the operations permitted it. Otherwise I have only used for my determinations vessels and tubes of Bohemian glass. Berzelius has frequently cast doubts upon the inalterability of the vessels employed in analysis. According to my experience this doubt is well founded. I have, in fact, found that the weight of tubes, retorts and flasks, even of hard Bohemian glass, is changed very appreciably either by the action of flame or of chemical agents which are ordinarily considered to be without action on them. Without any exception whatever, all glass, when long heated to redness in a spirit or gas flame, slowly but constantly diminishes in weight.

This loss may reach 35 or even 40 milligrammes in the space of two hours when a tube of Bohemian glass 50 or 60 centimètres long is exposed to a decided red heat in a gas flame. The same glass preserves, on the contrary, a constant weight when it is heated to the point of softening and bending under its own weight, away from the flame, either by means of charcoal—taking care to keep the ashes from touching the tube—or in a bath of pure magnesia which completely surrounds it. It will be seen further on, when analysing chlorate of potash, that I have heated, for an entire day, tubes and flasks of Bohemian glass even to the point of rendering them milky and white without in the least altering their weight. The magnesia bath has rendered me great services. In it I have heated to redness not only glass but also the platinum vessels in which my determinations have been made. A wash with water acidulated with hydrochloric acid completely removes the traces of magnesia always adhering to glass or platinum which has been heated in contact with it. Were it not for this bath, I should have had to give up, in a great many cases, the employment of gas as a source of heat. As far as I know, M.M. Erdmann and Marchand were the first to employ magnesia for keeping surfaces away from the contact of flame.

I have sufficiently proved that at temperatures below 300° or 350° C. neither nitric nor hydrochloric acids exert any action upon Bohemian glass, nor in general upon any hard glass perfectly free from alumina and excess of alkali.

Flasks of Bohemian glass, after having been used for a considerable number of syntheses of nitrate of silver, nitrate of lead, and chloride of lead, have preserved their original weight almost absolutely. The very slight altera-

tion which they may have experienced proceeds rather from the friction of the stopper, which is ground into the neck with emery, rather than to the action of acids.

Retorts, globes, and flasks, of common glass, yield even at the ordinary temperature, traces of their basic constituents to hydrochloric and nitric acids.

Experience has shown that sulphuric and hydrochloric acids, as well as the vapour of sal-ammoniac, attack all kinds of glass at a red heat.

The Agents Employed in the Determinations.—

It was not only necessary for me to have vessels capable of withstanding the action of the agents used therein, it was also needful that these agents should not bring with them ingredients capable of altering, either as to weight or composition, the bodies of which it was desired to determine either the formation or decomposition.

The intermediate bodies employed in my experiments have been water, hydrochloric, nitric and sulphuric acids, and sal-ammoniac. I confess that previous to undertaking this long work I had been completely mistaken as to several of the difficulties which had to be overcome before I could procure these bodies in a state of purity. Berzelius in his work on the atomic weights¹ has already mentioned the difficulty of obtaining liquid hydrochloric acid which would not leave a residue upon evaporation, and even confessed that he could not himself arrive at this result.

I, therefore, give here the experiments which I have made, both the methods which I have devised to procure these bodies in a pure state, and the means employed to ascertain this purity.

Water.—Either rain or spring water, twice distilled, taking care the second time to condense the steam in a platinum refrigerator, yields a liquid which, when evaporated immediately afterwards in a platinum vessel, either covered or freely exposed to the air, volatilises without leaving the slightest residue. This same distilled water, after having been kept for some days in a platinum or porcelain vessel, and then evaporated, leaves a very appreciable brownish-yellow residue, which burns away completely at a red heat in the air. Distilled water, which would volatilise completely in a covered or open vessel, if acidulated with pure hydrochloric or nitric acid, then leaves, when evaporated in a covered or open vessel, a yellow residue.

Distilled water contains, therefore, volatile organic matter, which, after a certain time, becomes spontaneously fixed, and becomes instantly so under the influence of nitric or hydrochloric acids.

When the presence of organic matter, fixed, but capable of destruction by heat, offered no objection, I made use of water twice distilled, and condensed the second time in a long platinum tube properly cooled. In the other case, at the first distillation, I slowly passed the vapour through a long copper tube, luted with clay and sand, completely filled with oxidised copper turnings, bent in a zigzag manner, and heated to a decided red heat in a furnace. The water resulting from the condensation of this vapour was re-distilled a second time and condensed in a platinum refrigerator. This refrigerator is a long platinum tube, soldered with gold, bent into the form of a syphon, and employed in a manufactory to conduct and cool the vapour of boiling concentrated sulphuric acid. This water, either immediately after its preparation or after being kept a long time in a stoppered flask, if submitted to evaporation by itself, or

acidulated with nitric acid, always volatilises in a covered vessel without leaving any trace of residue.

Hydrochloric Acid.—The liquid hydrochloric acid which I have made use of was obtained by conducting hydrochloric acid gas, by means of a Bohemian glass tube, into water deprived of all matter, fixed or capable of becoming so, and contained in a platinum tube. The hydrochloric acid gas was disengaged by the action of heat upon the pure liquid acid, such as is met with in the laboratory.

The acid thus obtained can be evaporated to dryness in a platinum retort without leaving the least trace of residue. If the evaporation is effected in an open vessel, the matters floating about in the air are always fixed by the acid, and then the purest product will leave a yellow residue, in which iron is often found. The testing of hydrochloric acid should, therefore, be done out of contact of air, contrary to the plan usually adopted.

Nitric Acid.—To procure absolutely pure nitric acid, I heated the commercial acid, sp. gr. 1.500, until the condensed product contained no chlorine.² The nitric acid thus obtained was twice re-distilled, and preserved in flasks. When I desired an acid leaving absolutely no residue, I re-distilled the purified acid a third time in a large platinum retort, employing a globe of Bohemian glass as a receiver. The acid was always used immediately after its preparation. I test its purity by operating on a whole litre. It evaporates in a platinum retort without leaving the slightest residue, when its vapour is carefully guarded from contact with the air.³ If the air has free access to it, the acid always leaves a more or less appreciable yellow residue, exactly as we have seen in the case of pure hydrochloric acid and pure water acidulated with acids, when evaporated without guarding them from atmospheric impurities. According to my experience, I am led to believe that the impurities found by most chemists in acids do not always pre-exist there, but have been communicated to them by the air having free access to them during the assay. *For this reason I have been obliged to perform my assays in platinum retorts fitted tightly to a Bohemian glass receiver; and all the evaporations of acid liquids have been performed in close vessels so as to prevent the air from penetrating into the interior of the vessels containing the liquid undergoing evaporation.*

Sulphuric Acid.—To obtain this quite free from all fixed principles, I distilled the commercial acid in a luted glass retort. The acid so prepared was re-distilled by small portions at a time in a platinum retort, taking the precaution to volatilise the liquid without allowing it to boil. As a condenser I used tubes of platinum soldered together with gold, the ends being ground so as to fit tightly one within the other. The acid was collected

² The assay of fuming nitric acid for chlorine requires that it should be previously mixed with four or five times its volume of water. Indeed, an acid at its maximum of concentration can contain traces of chlorine without being rendered turbid by nitrate of silver solution. This is easily seen by adding nitrate of silver to pure water and then mixing a few drops of this solution with nitric acid, which contains traces of chlorine. The acid will remain clear, but by adding to it the remainder of the water, the liquid will be seen to be decidedly turbid.

³ Platinum vessels are not suitable for the preparation of pure acids until they have been freed from the iron which ordinary manufactured platinum always contains. The best way which I have found for arriving at this result is to cause the vapour of dry chloride of ammonium to react upon them at a red heat. As long as the chloride of ammonium is slightly coloured yellow, it is certain that the metal contains iron. The platinum in this manner becomes dull-looking and much whiter. Before weighing the vessels so purified, they must be polished. It suffices for that to put them in a lathe and burnish them by means of an opal. All my platinum vessels have been treated in this manner.

and preserved in a platinum crucible until required for use. It never left a trace of residue when evaporated in a platinum retort.

Sal-ammoniac.—I will detail subsequently all the precautions which I have taken to obtain sal-ammoniac absolutely pure.

Carbonate of Soda.—Carbonate of soda, deprived of alkaline chlorides and sulphates by successive crystallisation, always contains iron. To remove this metal the salt was dried and heated to dull redness in a silver dish. After cooling, the anhydrous carbonate was added to a quantity of cold water insufficient to dissolve it. The solution was evaporated in a silver dish, and the residue dried and calcined a second time. This treatment was repeated until hydro-sulphuric acid no longer coloured the solution of the carbonate green. I have been obliged to repeat three times the successive action of heat and water to obtain this result. Carbonate of soda so purified still contains silica.

(To be continued.)

Experiments on the Best Mode of Correctly Estimating the Per-centage of Alcohol Existing in Wines, by JOHN HORSLEY, F.C.S. Lond., Analyst to the County of Gloucester.

FIRST note the specific gravity of the wine to be tried, say that compared with distilled water at 1000 it is .997, or 3 short of that number; then take 5 fluid ounces of the wine and evaporate it by rapid boiling in a sufficiently capacious flask to 2 ounces; then place the flask in a pan of water for a short time to cool. By this operation you will have expelled not only all the spirit, but a good portion of water with it.

Next make this residuary liquor containing the sugar and other extractive matter of the wine, minus its alcohol, up to the original bulk with distilled water, and take its specific gravity, which in this case will be 1.020. If this excess of 20 over the weight of the standard of distilled water be deducted from the specific gravity of the wine thus,—

.997 including its spirit, water, and other extractive matter of the grape;
20 amount of extractive matter in the water only;

.977 will be the true specific gravity of the spirit and water contained in the wine, minus the extractive matter, which is equal to 17 per cent. of alcohol, according to the published tables of alcoholic strengths at different densities and temperatures. Or, which is nearly the same thing, we may proceed by subtracting the specific gravity of the wine, .997, from the residuary liquor, thus 1.020

997

leaving .23, which, deducted from the standard of distilled water 1000

23

leaves .977 as the true specific gravity of the spirit and water in the wine.

These examples may be further verified by a distillatory experiment thus:—Take 5 ounces of the wine; distil off exactly half by a gentle heat from a graduated retort to which a receiver is connected till oiliness ceases to form in the tube end of the retort, indicating that all the alcohol has passed over. The specific gravity of this distillate (consisting of spirit and water) will be

·955, equal to 34 per cent., which, divided by 2,—as only half the bulk has been drawn over, gives 17 per cent. Or the distillate may be diluted with its own bulk of distilled water up to the original 5 ounces, when its specific gravity will be ·977, equal to 17 per cent. of alcohol.

This per-centage may be converted into Revenue proof spirit by rule of three sum, thus:—

Alc.	Wat.	Alc.
As 49	: 51	: 17 = 17·69 water
		17 alcohol
Proof . . .		34·69

TECHNICAL CHEMISTRY.

On the Artificial Colouring Matters derived from Aniline, by M. E. KOPP.¹

In the abstracts of the papers by M. Kopp, which we published in vol. ii. of the CHEMICAL NEWS, a general history was given of the production of aniline, and the various processes adopted for obtaining the coloured derivatives of that body. M. Kopp now passes in review several Memoirs that have been published in France on the Chemistry of the Colouring Matters. This, he remarks, is still extremely obscure; and none the less so that in these Memoirs there are not only wide disagreements in the theoretical views entertained, but differences as to simple facts, and difficulties and contradictions to be met with in the writings of the same author. We shall give a short summary of these papers, at the risk of repeating once or twice what has already been published in the CHEMICAL NEWS.

The first paper noticed is M. Guignet's "Researches on Fuchsine." This substance is obtained in the form of a viscous mass, which in time becomes almost completely solid. It gives a bright red solution with alcohol, both absolute and somewhat diluted; it is also slightly soluble in ether and sulphide of carbon. It is soluble in boiling water, but on cooling it is deposited in reddish-brown scales, which do not appear to have a definite crystalline form. Nitric acid dissolves it, forming a yellow solution, which, on being diluted with water, becomes red. It gives a precipitate of chloride of silver with the nitrate, showing that the solution contains a hydrochlorate. (M. Guignet regards fuchsine as a mixture of a peculiar base with its hydrochlorate.) The nitric solution evaporated at a low heat yields well-formed prismatic crystals, of a deep brown colour. Water and alcohol partially decompose these crystals, giving a red solution; but a part of the salt crystallises again without having undergone any change.

Strong sulphuric acid decomposes fuchsine, disengaging an abundance of hydrochloric acid vapour. It forms a yellow solution, which, on cooling, becomes a mass of yellow plates, like mica. These plates appear to be an acid salt. When the solution is carefully saturated with carbonate of baryta, another sulphate is obtained, which crystallises in colourless needles. Lastly, hydrochloric acid dissolves fuchsine, forming a yellow solution, which yields brown prismatic crystals. All the above solutions are precipitated when they are exactly saturated with ammonia. Carmine-red flocculi are deposited, which are slightly soluble in water, and freely soluble in alcohol. In contact with an excess of ammonia

or caustic potash these flocculi are completely decolorised and changed into a white insoluble matter, which, however, re-assumes its red colour when treated with water or acids. The same is observed with stuffs dyed with fuchsine. The colour is discharged by caustic potash, but re-appears when the tissue is washed with water or treated with an acid.

M. Guignet expresses an opinion that fuchsine may have the composition $C_{17}H_7ClN_2$, and be analogous to nitrazophenylamine, $C_6H_5(NO_2)N_2$. This opinion, however, is not shared by M. Kopp, who observes, that the fuchsine of MM. Rénard and Franc is a very complex substance; and it is possible that many of the reactions described by M. Guignet, and some of the crystallised bodies he has observed, are derived, not from the colouring matter itself, but from the bodies which accompany it. The experiments should be repeated with fuchsine purified by the process of M. Schneider—which we shall presently describe—or with the colouring matter obtained from wool or silk previously dyed.

The ideas of M. Bechamp on the formation of fuchsine next quoted by M. Kopp, we have already given at p. 311, vol. i., and p. 215, vol. ii. We need not, therefore, repeat them here. The properties of fuchsine he describes as follows:—It is an organic base, slightly soluble in water, having the formula $C_{24}H_{10}N_2O_2$. In the hydrated state it is of a deep red colour. When pure, as it is obtained by precipitating the alcoholic solution with ether, it appears in form of non-crystalline scales of a brilliant metallic green colour. The aqueous and alcoholic solutions, and the solutions in wood spirit and acetone are red. It forms uncrystallizable salts, the solutions of which are red when they are neutral, and yellow with an excess of acid. Sulphurous acid slowly decolorises the solution, but by concentration at a gentle heat the colour is restored. With hydrochloric acid it forms two kinds of salts—neutral and acid—the former ($HCl + C_{24}H_{10}N_2O_2$) is red, and gives a red solution; the second ($2HCl + C_{24}H_{10}N_2O_2$), obtained by passing hydrochloric acid gas over the hydrated fuchsine dried in a vacuum, is of a cinnamon brown colour, and gives a reddish-brown solution. Experiment gave 17·3 and 15·25 per cent. of acid in the neutral salt; calculation requires 15·6 per cent. The same salt gives a purple precipitate with chloride of platinum, which dissolves in alcohol, giving a violet red solution. The formula of the precipitated salt is $PtCl_2 + C_{24}H_{10}N_2O_2.HCl$. This formula requires 24·26 per cent. of platinum. Experiments gave 24·43 and 24·56 per cent. of platinum.

Bechamp's views of the formation and constitution of fuchsine have been combated by Barreswil, who has shown that fuchsine is a non-oxygenated body. In fact, by operating with perfectly anhydrous bichloride of tin and aniline under circumstances in which it was impossible for air or moisture to reach the materials, he made fuchsine. The formula of M. Bechamp, therefore, cannot be exact. It is, moreover, contradicted by the fact that fuchsine is generated when aniline is treated with iodine, bromine, sesquichloride of carbon, and iodoform, neither of which contains oxygen nor reducible bases.

MM. Persoz, de Luyne et Salvétat, in their report on aniline red, have pointed out a number of facts. They first verified the production of the red colouring matter by heating an hydrous bichloride of tin with aniline, and also with the hydrated bichloride, protosulphate of tin, iodoform, iodine, mercurous, uranic, and ferric nitrates, and the fluoride of tin. When operating with 8 kilogrammes of aniline and 4 kilogrammes of anhydrous bichloride of tin, they obtained in twenty minutes

¹ Abridged from the *Moniteur Scientifique*.

a pasty mass of a bright red colour. By boiling together for one hour 4.2 kilogrammes of aniline and 2.3 kilogrammes of mercurous nitrate, they obtained a syrupy substance of a violet-red colour. They also made the colouring matter by means of arsenic acid, and proved that in this operation the arsenic was not reduced to arsenious acid, and yet that nearly the whole of the aniline was transformed.

Their ideas on the formation of fuchsine are the following:—It is not a product of the oxidation of aniline, but the result of a molecular change in that body, occasioned by the presence of various chemical agents. To effect this molecular change, it is necessary to employ a temperature of from 180° to 200° C. Indisine, or the violet colouring matter, on the contrary, is an oxidised product, the formation of which is always accompanied by the production of a good deal of resinous matter. From this it results that when non-oxidisers are employed, only fuchsine is formed, while oxidising bodies induce the formation of indisine, but in relatively small proportions, under even the most favourable circumstances.

(To be continued.)

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, October 1, 1861.

E. W. BINNEY, F.R.S., F.G.S., Vice-President, in the Chair.

A letter from Dr. Fairbairn, F.R.S., &c., tendering his resignation of office as one of the Vice-Presidents of the Society having been read, it was moved by Mr. SPENCER, seconded by Mr. J. A. RANSOME, and unanimously resolved, "That the Members of the Literary and Philosophical Society express their regret that Dr. Fairbairn feels it necessary to resign his Vice-Presidentship of the Society, and hope he will still continue to favour them with his presence and his valuable contributions as formerly."

Dr. SCHUNCK, F.R.S., &c., was elected a Vice-President, in place of Dr. Fairbairn, F.R.S.

Mr. Alfred Fryer was elected a Member of the Council in place of Dr. Schunck, F.R.S.

Dr. SCHUNCK announced to the meeting that Messrs. Spence; Roberts, Dale, and Co.; Tennants and Co., and others had, at his request, presented to the Society a portion of the beautiful products which had formed part of the interesting exhibition in the laboratory of Owen's College during the late meeting of the British Association.

It was moved by Dr. SCHUNCK, seconded by Dr. CLAY, and unanimously resolved, "That the thanks of the Society be given to the donors of chemical products."

Mr. BAXENDELL, F.R.A.S., read a Paper entitled "Observations of Comet 1, 1861."

Although this comet was not at any time a very conspicuous object to the naked eye, yet some of the features which it presented when viewed with a good telescope at the time of its greatest brightness were sufficiently remarkable to render it an object of peculiar interest to the astronomer; and I have therefore thought that a brief account of the observations made with the excellent instruments of Mr. Worthington's observatory might be acceptable to the members of this Society.

My first observation was made on the night of May 3, 1861. The comet was then already visible to the naked eye as a dull hazy-looking star of the 4½ magnitude. At 10h. 17m. 48.7s. G.M.T. a comparison with the star *Arg.*

178,8=190,112 made with the equatorially-mounted achromatic of 5 inches aperture, and a dark field photographed micrometer constructed by Mr. Dancer, gave the comet's apparent place R.A. 10h. 5m. 27.76 Dec. + 48° 52' 7.7". Turning the 13-inch reflector upon the comet with powers of 81 and 196, it was found that the nebulousity was more than 20' in diameter, considerably condensed in the middle, but without any distinct planetary or stellar nucleus. There was a faint tapering elongation extending about a quarter of a degree from the north following side, and stars of the 11th and 12th magnitude were easily seen through the comet at the distance of half a radius from its centre.

May 4.—Three comparisons with *Arg.* 173,122 gave the place of the comet at 9h. 26m. 19.3s. G.M.T. R.A. 9h. 52m. 19.83s. Dec. + 45° 18' 28.1".

With the 13-inch reflector the diameter of the nebulousity constituting the head of the comet, carefully estimated by comparison with the known diameter of the field of view, was 22'. It was much condensed in the middle, but there was certainly no distinct stellar nucleus. The centre of greatest condensation was not in the centre of the nebulousity, but towards the north following side. The tapering elongation of last night was now a narrow and slightly fan-shaped tail of 2½ degrees in length, but apparently separated from the nebulousity of the head by a remarkable and comparatively dark interval. The point of origin of this singular tail was estimated to be from 12 to 15 minutes distant from the centre of the head, and its breadth at this part was about 4½ minutes, and at its extremity about 15 minutes. Its axis was perfectly straight, and its brightness was greatest at the narrow end, where it was equal to that of the nebulousity of the head at two-thirds of the radius from the centre.

May 5.—At 10h. 16m. 59.7s. G.M.T., six comparisons with *Lalande's* 19168 gave the comet's apparent place R.A. 9h. 39m. 37.82s. Dec. + 41° 21' 34.5".

The sky to-night was not very favourable for the observation of faint objects, but the general features of the comet did not appear to have undergone any material change. Last night it occurred to me after leaving the observatory that the axis of the tail was not exactly in the direction of the comet's radius vector, and to-night I found its angle of position at 13h. 35m. sidereal time to be 96.7°. At this time the position of the sun and comet were:—

The sun R.A. 42° 54' — N.P.D. 73° 33'.

The comet R.A. 144° 50' — N.P.D. 48° 43'.

From these data we find that the angle of position of a prolongation of the comet's radius vector, was 69.9°. The apparent deviation of the axis of the tail was therefore 26.8° in the direction of the comet's motion.

May 7.—At 12h. G.M.T. the comet appeared to the naked eye to be nearly equal to μ Leonis, and equal to, if not brighter than, 38 *Lyncis*.

May 9.—Three comparisons with *Lal.* 17,987 gave the comet's apparent position at 9h. 57m. 30.5s. R.A. 9h. 3m. 23.25s. Dec. + 26° 11' 26.1".

At 13h. 15m. sid. time the angle of position of the axis of the tail was 103.2°. At this time the angle of position of the comet's radius vector was 74.5°; the deviation therefore amounted to 28.7°.

With the 5-inch achromatic the tail appeared to be half a degree in length; but with the 13-inch reflector it was fully one degree, though fainter than when last observed, and still much less in breadth than the diameter of the head. The average diameter of the head was about 20', but the nebulousity extended farther on the south preceding side of the point of greatest condensation than on the north preceding or north following sides. There was still an entire absence of any stellar nucleus. To the naked eye the comet appeared as a star about equal in brightness to μ Leonis.

May 14.—Notwithstanding the moonlight, the comet was

still visible to the naked eye, and in the 5-inch achromatic with a power of 68 it was about 10' in diameter. The tail, however, could not now be seen.

May 17, 10h. 25m. The comet, though at a very low altitude and with strong moonlight, was still very easily seen with the 5-inch achromatic, and did not appear to have diminished since the 14th inst. This was the last opportunity I had of observing it.

Lalande's stars Nos. 19168 and 17987 occur in Bessel's Zones Nos. 454 and 347, and Bessel's places have been used in making the reductions.

Some remarks having been made by Mr. ATKINSON and Mr. VERNON respecting the vibrations of the barometric column which frequently take place during gales of wind,

Mr. FRYER stated that, with a view of ascertaining whether the barometer was subject to minute oscillations inappreciable by the ordinary method of observing, he had placed an aneroid barometer under the microscope, using the quarter-inch object glass, and by bringing one of the strise on the surface of the steel index into focus, he was able, by means of the micrometer, to observe a movement of the 20,000th of an inch. The index appeared to be in constant motion, but at present he was not prepared to lay any set of observations before the Society. Mr. Fryer also suggested, for the same purpose, the use of a barometer filled with the oleine of olive oil, such an instrument being free from the disturbances caused by the watery vapour present in the water barometer and exhibiting a greater range.

PHYSICAL AND MATHEMATICAL SECTION.

April 25, 1861.

Mr. MOSLEY read an extract from a letter received by him from Dr. Martin, of Lisbon, in which were enclosed a series of meteorological observations taken at that place, from the 6th to the 12th February last, both inclusive.

Mr. VERNON produced a printed series of meteorological observations made at Sydney and Paramatta, in 1857, 1858, and 1859 which he presented to the Section.

Mr. BAXENDALL gave details of observations which he had made during the last few days on a large and remarkable solar spot, in which the secondary penumbra had been plainly visible, and had been observed by him to consist of a fine net work of bright lines. The penumbra was strikingly striated, and the middle of the nucleus had been occupied by a bright spot detached from the penumbra at first, but afterwards joined to it, as the spot began to close up, by one of the projecting spurs usually observed to occur in decaying spots. For the purpose of the observations a trough filled with sulphate of indigo was placed in the cone of rays coming from the large mirror of a Newtonian reflector of seven inches aperture, before they reached the eyepiece. The sun's image was a deep red colour, but the definition was very good.

Professor CLIFTON suggested that the unusual visibility of the secondary penumbra in this case might arise from its being so coloured as to be rendered more visible than usual by the use of the sulphate of indigo.

July 27, 1861.

Mr. BAXENDALL read a Paper entitled "*Observations of Comet 1, 1861.*" [This Paper was afterwards read at the Ordinary Meeting of the Society, held on October 1, 1861.]

Mr. BAXENDALL also read a note "*On a Solar Spot of Long Duration.*"

At the last Meeting I exhibited a sketch made on April 24, 1861, of a solar spot in which the secondary penumbra had been seen with unusual distinctness. This spot has since twice crossed the visible disc of the sun, and has had a term of existence considerably above the ordinary average. It was first seen on April 17, near the eastern limb of the sun, and was then a fine spot of not less than the third magnitude, and after undergoing many consider-

able changes of form and structure, was finally observed very near the western limb on June 21, as a spot of only the 9th or 9½ magnitude, and from its previous rate of decrease it is probable that it would become entirely extinct in four or five days afterwards. Its duration, therefore, would not be less than 70 days, and it thus affords a striking instance of the fact that frequent and extensive changes of form and structure do not necessarily tend to produce an early extinction of a spot. Between April 20, at 5h. 13m. G.M.T., and June 15, at 5h. 30m. it moved through 783.3 degrees of longitude, or at the rate of one sidereal revolution in 25.74 days. On April 20 its heliographical latitude was 14° 11' N., and on June 15 14° 2' N. These results indicate a direction and rate of drift which agree very nearly with the results which Mr. Carrington has obtained for other spots in and near the same parallel of latitude.

NOTICES OF BOOKS.

A Manual of Qualitative Analysis. By R. GALLOWAY, F.C.S. Professor of Practical Chemistry in the Museum of Irish Industry. Third Edition. London: John Churchill, 1861.

In the preface to the second edition of Mr. Galloway's Manual, the author describes in some detail the method of teaching Chemical Analysis which he has found to answer best. The comparatively rapid sale of his work, and the appearance of a new and improved issue, at the present time, when so many other volumes on the same subject have been published, seem to demand a careful notice of the points in which Mr. Galloway's plan differs from other plans. We propose therefore to criticise the account which the author gives of his own scheme of analysis, and the way in which he wishes it to be used (pp. vi., vii., viii.)

He says:—"In all other works on Chemical Analysis with which I am acquainted, the properties of the bases and acids, and the application of these properties to the analysis of substances, are treated separately. As a consequence, the student, when he goes through the experiments on each base and acid, performs these illustrations of the properties, without perceiving their use or application." This objection is easily obviated, if those properties of each base and acid which are actually made use of in analysis be distinguished from the others by a different type, at the same time that all the compounds mentioned under one acid or base are mentioned under all others, even if they are soluble. This plan has not yet been adopted in more than one Analytical Treatise, so far as we know.

Mr. Galloway proceeds:—"In the part of the work devoted to the Analytical Course, he is told what to do, either by tables (as in 'Giessen Outlines,' and some other works,) or, as in Fresenius, by a more tedious, and, in my opinion, as defective a method. The principles upon which these instructions are based, are not given with the instructions, but in a separate chapter of the work; and, unless the student is able himself to unite the two,—the principles which the practical instruction,—he becomes a mere analytical machine." Here we think that our author depreciates too much the methods of other teachers of the analytical art.

The student is generally first taught the chief features of the bases and acids, the most characteristic compounds of each base and acid having been specially pointed out to him. This done, and a broad view of the whole subject having been acquired, he proceeds to utilise his knowledge by the application of particular facts in the actual course of analysis. He has already learnt the distinction between group and special tests, and will find no difficulty in seeing why such and such re-agents are used in different cases.

We concur in Mr. Galloway's opinion of the plan adopted by Fresenius. There can be no doubt about its being tedious and difficult. The objection to tabular statements of analytical plans entertained by the great German analyst, seems almost morbid. Whether they appear as tables or not, analytical operations can only be represented in tabular statements. Those given by Fresenius are merely spread over some two or three pages, somewhat vaguely, instead of being concentrated in a systematic and intelligible form on one page only. Fresenius' plan is less costly to print, but, at the same time, more difficult to understand. One can scarcely work through a few pages of his "System of Instruction in Qualitative Analysis" without meeting with such delightfully complicated directions as this,—"Test for cobalt and nickel, as directed, § 192, 1, b, β , $\beta\beta$, (149)."

Mr. Galloway characterises the ordinary system as difficult as well as defective; he says, "It is so difficult, that those who employ it generally teach one thing, useless in itself, in order that they may teach another; they teach the student first to look for one acid and one base—a limitation which is not adopted in actual practice—solely for the purpose of rendering the course in which they have [?] he has] to look for all the bases and acids less difficult." We do not think it quite useless for the student to be able to detect one acid and one base; the principle of progressive exercises is one universally adopted, even by Mr. Galloway himself, who recommends the student to examine each group by itself—why not, then, each individual member?

Our author proceeds thus:—"In the plan I have adopted, the properties of the different members of each group are contrasted by placing them in parallel columns; the advantage of this is, that the student, after he has performed the experiments, is able himself to devise methods for the detection and separation of the different members; it places him, in fact, in the position of a judge who has to decide some cause after having heard all the pleadings." The plan here referred to consists merely of a further development of the plan of tabular statements. Mr. Galloway speaks of the reason and judgment exercised by the student using these tables. We think that the behaviour of the various bases and acids ought to be ascertained in a less narrow way, as pointed out above, and that the tables of properties are not unlikely to assist in making the student an "analytical machine." A careful selection of reactions ought to be presented to the beginner under each base and acid, while the analytical schemes subsequently given, ought not to do much more than suggest how the general and special tests may be successfully applied in the detection of the substances met with in analysis. The tables showing the reactions of the various bases and acids are very full, and present, without doubt, much information in a small compass, but they are not peculiar to the present Manual, and have been largely employed in other works.

Those features of his Manual to which Mr. Galloway specially directs attention, do certainly enable a student to acquire the power of performing analyses more rapidly and more easily than the ordinary system does: whether this power rests upon as secure a foundation of knowledge, is a matter of doubt.

The present edition is brought down in every important particular to the state of analytical knowledge at the present time. The photo-chemical method of Cartmell and the spectrum experiments of Bunsen will be found described very clearly and fully. Many of the special tests recently introduced into the laboratory, such as the excellent method of separating cobalt and nickel by means of nitrite of potash, will be here found in their proper places. We do not find, however, any reference to the use of binoxide of lead as an oxidizing reagent, although it is found extremely useful, in conjunction with nitric acid, for detecting traces of manganese carried down in the

ammonia precipitate (Group iii.), and for ascertaining the presence of chromium in the same precipitate. In the latter case a small portion of the precipitate is boiled with binoxide of lead in the presence of a solution of potash, chromate of potash being thus formed. We have not been able in actual practice to carry out quite successfully Mr. Galloway's table for the analysis of Group iii.; we do not think that much reliance should be placed upon the solubility, when iron is present, of sesquioxide of chromium in cold soda-solution taken in connection with its subsequent precipitation on boiling.

With a few trifling exceptions, such as those we have noticed, the book is a thoroughly good Manual of Analysis, and can be mastered in a short time. It is highly appreciated in several large schools, and is found of very great use by Medical students.

Report of the Committee on the Decay of the Stone of the New Palace at Westminster.

THIRD NOTICE.

IMMEDIATELY following the examination of Mr. Szerelmey, the Committee were engaged in taking the evidence of Mr. Frederick Ransome, of Ipswich. It will be remembered that these gentlemen have urged rival claims in regard to the application of their respective processes to the Palace at Westminster; they were the first to undertake experiments in connection with the preservation of the stone actually forming part of the building; the results arrived at by them were capable of closer scrutiny and of more minute inquiry, and assumed, therefore, on this account a greater importance as compared with other and later suggestions which had not yet to the same extent been submitted to experimental trial.

During the month of August, 1859, the processes of Mr. Szerelmey and Mr. F. Ransome appear to have been first brought into direct competitive examination. At that period Sir Charles Barry sanctioned the treatment of the two bays on the river front, which were to be prepared each as an illustration of the capabilities of the process, with the view afterwards of applying on a larger scale that which should prove more successful in the preliminary trial. These specimens of protective workmanship have been reported on at the instance of the Government conjointly by Sir Roderick Murchison and Professor Faraday; been again inspected by the present Committee, and so frequently have formed a topic of discussion in the public journals, that it is needless now to remark more than the simple circumstance that the peculiar whitish appearance of Mr. Ransome's bay has been objected to, and that slight indications of efflorescence have made themselves apparent.

A still earlier application to the Houses of Parliament of the then recently patented process of Mr. Ransome dates as far back as the autumn of 1856, but the examples of that early period are not accounted by the inventor as successfully representing the capabilities of his mode of treatment from their having been the very first outdoor experiments of the kind, and executed without a full knowledge of all the requirements. The earliest, and at the same time satisfactory, example of the process is afforded by the Baptist Chapel, Bloomsbury, which was coated in the year 1858. The whole front of the chapel is of Caen stone, which, prior to the application of the process, is said to have been in a state of very rapid decay. Mr. Ransome refers particularly to the treatment of the Bath stone façade of the Royal Mews at Buckingham Palace as being the most successful example in London, but this having been executed so recently as 1860, cannot, we think, yet be considered as exhibiting a satisfactory indication of the value of his process. The Custom-house at Greenock, built of sandstone, is stated to be in every way a fair illustration. This was coated in 1859.

In regard to the nature of the process employed by Mr.

Ransome, we are in possession of the full particulars made known in the patent specification, and every information has most promptly been furnished by the inventor as to the materials employed and the mode of manipulation. The Committee appear also to have been assisted in their inquiries with reference to the solution of a problem of considerable experimental difficulty, viz., the determination of the depth to which the chemical preparation actually penetrates the substance of the stone. This point has not yet been properly ascertained, and we propose later to take an opportunity of resuming the discussion on this question, which will be more appropriately introduced after the nature of the materials themselves has been announced.

The object of Mr. Ransome's process is to deposit by precipitation within the pores of the stone an insoluble silicate of lime; this compound consisting wholly of imperishable mineral constituents, is intended to afford protection to the stone by rendering it less absorbent for water, and by preserving it likewise from the influence of the atmosphere. Such insoluble compound is formed by double decomposition between silicate of soda and chloride of calcium, applied as solutions and in this order to the surface of the stone. It will be seen, therefore, that besides the insoluble silicate of lime, an equivalent proportion of chloride of sodium must always be produced, and it appears probable that to this second product must partially be ascribed the tendency already referred to of causing an efflorescence on the outside faces of the stone. It was found to be possible to construct a block or kind of artificial stone from powdered materials, moistened alternately with these two solutions, and the property possessed by such blocks of resisting for a time the action of water, was conclusively demonstrated by the inventor. So great indeed is the degree of protective action communicated by the presence of the calcareous silicate, that limestone which has been thoroughly coated with this substance, is said to remain unacted upon when immersed in weak acids. In proceeding to the manufacture of "artificial stone," modes of operating have been resorted to for the formation of a compact mass, which are no longer similarly applicable to the walls of the Houses of Parliament; thus Mr. Ransome describes the interesting results obtained by exposing to heat the mixture of materials above referred to, whereby varieties of even greater insolubility were produced.

The objection which does not appear to have been conclusively answered in regard to this process, has reference to the impracticability of producing by double decomposition, especially when one of the secondary products is soluble in water, a condition of surface which is totally unaffected by the rain or moisture of the atmosphere; thus it would appear difficult so thoroughly to close the pores of the stone, as to prevent the extraction of the chloride of sodium by water coming in contact with the face of the block. If removed, cavities, gradually widening, must be formed in consequence, which would permit of a subsequent and progressively increasing action upon the stone, due to the admission of the atmosphere. Moreover, the silicate of lime itself is a precipitate, somewhat gelatinous in nature, and occupies more bulk when moist, or at the time of its formation, than when it eventually becomes dry and sinks in the pores of the stone.

NOTICES OF PATENTS.

391. *Manufacture of Paper from a Pulp obtained from Wood.* E. H. BARRÉ and C. M. J. BLONDÉL. Nantes, France. Dated February 16, 1861.

This invention relates to an improved method of effecting the disintegration of wood for the purpose of obtaining therefrom ligneous fibres suitable for the manufacture of

coarse paper. The patentees employ as the agent for facilitating the separation of the fibres nitric acid; but inasmuch as the strong acid would be liable to act too energetically upon the substance of the wood, it is preferred first to saturate the shavings or sawdust with water, and then to proceed to the treatment with nitric acid. In this manner the structure of the wood is softened, so that little mechanical aid is required to reduce it to the condition of supple ligneous fibre, and after a thorough washing, the material is ready for bleaching and general treatment like any ordinary paper pulp. But, with a view of economising the nitric acid, and at the same time obviating the inconvenience arising from the corrosive action of the acid in the wood upon the metal of the crushing rollers, it is preferred to convert the free nitric acid into nitrate of soda by adding a sufficient quantity of carbonate of soda immediately after the acid treatment. By evaporating the washing liquors a crude nitrate may be recovered, which, although containing organic matter and other impurities, will serve admirably for the preparation of new supplies of nitric acid by distillation with oil of vitriol. As the result of the oxidation by nitric acid of the resinous matters in the wood, a certain quantity of carbazotic acid is generated, which, on the addition of alkali, produces a dark brown colour; the pulp loses much of this simply by squeezing in a press, and afterwards can be thoroughly bleached by washing and the treatment with chlorine. As a means of expediting the course of these operations, the inventors prefer to employ heat in some of the processes, but several hours' crushing are requisite for the production of the finer kinds of pulp.

The addition of carbonate of soda to the woody matters while the acid is yet retained in their structural cavities, would serve an important end, which is not alluded to in the specification, although several matters of inferior moment are deemed by the patentees worthy of the full scientific explanation therein given. The principle of subjecting a vegetable structure to the alternate action of free acid and an alkaline carbonate was one originally proposed, and very successfully carried out, in connection with the manufacture of linen from flax. It was found that the carbonic acid gas liberated as the result of this action was capable of exerting a considerable amount of disruptive force, which was useful in tearing open the structure, and in facilitating the subsequent mechanical treatment for the separation of the fibres. The mode of proceeding now described differs only in the detail of substituting an expensive acid for that formerly employed.

408. *Preparation of Alkaline and Earthy Cyanides.* W. CLARK, Chancery Lane, London. A communication. Dated February 19, 1861.

This patent refers to the production from ammoniac of alkaline and earthy cyanides and ferrocyanides. The process of conversion is effected by passing a current of ammoniacal gas over a mixture of a carbonate of one of these bases with charcoal, pitch, tar, or other reducing agent, heated to dull redness in any suitable furnace. The employment of crude soda and potash, which contain a certain quantity of caustic alkali in addition to the carbonate, is specified as being particularly well adapted for producing this chemical reaction. A second claim relates to the preparation of cyanides or ferrocyanides by the reaction of a soluble sulphate upon cyanide of barium formed as above, whereby a precipitate of sulphate of baryta is produced. And, thirdly, the partial reconversion of this precipitated sulphate of baryta into carbonate by reduction, in the first place, with charcoal at a high temperature so as to form crude sulphide of barium, and passing carbonic acid gas through an aqueous solution of this product, when a certain quantity of carbonate of baryta will be regenerated and may be used in a repetition of the process.

The chain of chemical reactions called into play in the

transfer of nitrogen from crude ammoniacal matters into cyanides and ferrocyanides, is highly interesting, and likely to be susceptible of advantageous employment. From the frequency with which large proportions of sulphate of baryta are employed in the adulteration of pigments, one is almost tempted to believe that the lower commercial qualities of Prussian blue might be directly procured by the precipitation of ferrocyanide of barium with persulphate of iron.

424. *Manure.* T. RICHARDSON, Newcastle-on-Tyne.

Dated February 20, 1861.

WITH the twofold object of producing a more concentrated and soluble variety of superphosphate manure, Mr. Richardson submits to a supplementary drying treatment the ordinary product of the action of sulphuric acid upon bones, bone-ash, coprolites, apatite, guano, and other commercial forms of phosphate of lime. The process is carried out simply by exposing the mass to a degree of heat sufficient to drive off the excess of water.

There would undoubtedly be a reduction both in bulk and weight, as the consequence of the expulsion of twenty per cent. or upwards of water from the ordinary superphosphate manure, and if care be taken in guarding the material from the action of an unduly high temperature, no loss of valuable constituents is to be anticipated. The volatilization of small quantities of ammonia might be the result of over-heating.

440. *Doctors, Calico Webs, or Scrapers.* A. CROOKES and H. ROBERTS, Sheffield. Dated February 22, 1861.

THIS invention consists in a method of protecting from corrosive influences the steel or other metallic surfaces of scrapers, and other parts of machinery employed in the printing of textile fabrics. These portions of metal are to be coated with silver, copper, or tin, by galvanic or other agency, that metal being employed in each instance which most effectually resists the action of the colours, or other chemical preparations brought into contact with it.

A suggestion so extremely simple must surely be capable of general application in many similar instances.

Grants of Provisional Protection for Six Months.

1692. Richard Jolley, St. John's Street, Smithfield, London, "An improved apparatus for heating, cooling, or drying, infusing, extracting, or absorbing vapours and gases for manufacturing, medical, or domestic purposes, and for preserving liquids and solids alimentary or otherwise."—Petition recorded July 3, 1861.

1956. William Clark, Chancery Lane, London, "Improvements in bleaching and clarifying saccharine matters, and in apparatus for the same."—A communication from Edouard Théophile de Gemini and Edmond Oswald de Gemini, Boulevard St. Martin, Paris.—Petition recorded August 6, 1861.

2197. Gustav Bischof, jun., Swansea, Glamorganshire, "Improvements in extracting copper and silver from ores containing those metals."—Partly a communication from Dr. Gustav Bischof, sen., University of Bonn, Prussia.—Petition recorded September 3, 1861.

2240. George Norris, Brondesbury Terrace, Kilburn, Middlesex, "Improvements in the manufacture of soap."—Petition recorded September 7, 1861.

2303. John Reeves, New York, U.S., "Improvements in electro-magnetic engines for obtaining and applying motive power."

Notices to Proceed.

1277. Robert King and Kenneth Robson, Granville Street, Sheffield, "Consuming and destroying smoke as emitted from engine or other chimneys, and from all other flues from which smoke is emitted."—Petition recorded May 18, 1861.

MISCELLANEOUS.

Arsenical Paper-collars.—Under the signature of *Author* (City), a letter has been addressed to us respecting paper-collars, which are now so extensively worn by gentlemen. He states that some arsenical preparation is employed in their manufacture, and a case has come under his notice in which a person has been injured by their use.—*Lancet*.

Blondin and Leotard at the Polytechnic.—The scientific principles upon which Blondin and Leotard perform their wonderful feats of balancing, receive from Mr. Pepper, the popular lecturer of the Polytechnic, an exposition which creates surprise on the part of his numerous and gratified auditory that what they have looked upon with wonder should be so simple. The art of balancing is shown by a variety of models and experimental and pictorial illustrations to consist in the preservation of the centre of gravity, which is found, for the purpose of demonstration, by applying the plummet, and drawing a straight line from the apex to the base of the object whose centre of gravity it is desired to determine. So long as the line of direction falls within the base there is no chance of a tumble, as was shown by reference to the famous leaning tower at Pisa, and by experiments with the wooden swords used by conjurors. Blondin on his rope at the Crystal Palace was then introduced, through the medium of photography and the microscope, and the use of his long balancing pole explained to the audience. A practical exemplification of the art is given, on a rope stretched across the platform by John Snell, waterman and boat-builder, of Hampton, who lately performed the difficult feat of walking across the Thames on a common towing rope. Snell walks backwards as well as forward, and carries a boy on his back. The trapeze feats, which have made Leotard so potent an attraction at Cremorne and the Alhambra, are also explained, and their principle shown to be identical with that of the pendulum.

ANSWERS TO CORRESPONDENTS.

F. L. Auld.—No answer to the communication has yet reached us.

J. P.—Your letter has been received, but we scarcely think its contents applicable to our columns.

Radiant Chemical Action.—A correspondent asks for information on this subject.

H. G.—Some of the constituents of rock-oil have been used in making soap, but not to any great extent. Most of the oils are unsuitable.

Peroxide of Hydrogen is prepared by adding a paste of peroxide of barium and water to a solution of hydro-fluosilicic acid. Filter through gum-cotton and concentrate by evaporation over oil of vitriol *in vacuo*.

Reginald R.—1. Any good chemical work will describe the way to make chloride of nitrogen, but you had better not try, unless you are a most expert manipulator, for almost everyone who has yet worked with it has been injured for life by its explosive violence. 2. We do not know. 3. Oxide of iron. 4. Griffin's gas-blast furnace.

Bluish Colour to Gun-barrels.—A correspondent wishes to know what chemical application will impart a bluish colour to gun-barrels. There is a method of imparting it so successfully that the difference cannot be detected between those newly done and those which have the colour imparted to them in their manufacture.

Iodide of Potassium.—Perhaps some of our subscribers will favour us with a reply to the following:—"Sir,—Can you inform me of the method generally adopted by the large manufacturers of iodide of potassium in the production of that salt, viz., what description and size of vessels it is evaporated in, and how heated, by steam or sand-bath? What quantities do they generally produce at one operation? Do they make their iodide of iron solution in large or small quantities, and how?"

J. A. Bower.—An electric light will be indispensable in exhibiting the phenomena to a large audience at once, but the plan generally adopted at lectures is to illustrate the remarks by coloured diagrams, and to exhibit the phenomena afterwards by means of small spectroscopes. We believe spectroscopes can be hired for the night, but you had better enquire of a maker.

THE CHEMICAL NEWS.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Note on Fluorine, by T. L. PHIPSON, Phil. Nat. Doct. Brussels University, Member of the Chemical Society of Paris, &c.

In 1857—58 I began a series of experiments in Paris, with the view of obtaining if possible the element fluorine. I have been constantly prevented from obtaining fluorine in a state of absolute purity chiefly on account of the impurities contained in the fluoride of potassium, permanganate of potash, and other substances which I had not then means of preparing myself in any quantity. The Parisian fluoride of potassium generally gave chlorine in abundance; so did the permanganate of potash, which I used with hydrofluoric acid to oxidise its hydrogen.¹ Indeed, I am led to believe that the ozone obtained by M. Boettger with permanganate of potash was simply oxygen mixed with chlorine. Some years ago (in 1856) I thought I had obtained ozone from permanganate of potash; but on introducing a little nitrate of silver into the gas, chloride of silver was immediately formed, and the odour and action upon iodide of potassium ceased.

Concerning fluorine, all I can say at present with certainty is, that it constitutes a colourless, incombustible gas, having a peculiar odour similar to that of oysters, a great affinity for water, which it decomposes in daylight, and having no action whatever upon glass. It whitens litmus like chlorine. It can be obtained by heating hydrofluoric acid with nitric acid in a retort, when fluorine is evolved, together with a certain quantity of nitrous vapours. If this experiment is made over water, a few nitrous fumes are at first perceived and a gas is evolved, but as soon as a certain quantity of fluorine is produced, the water rushes into the retort as if into a void; the whole apparatus is filled so quickly that it is impossible to perceive the passage of the liquid. This accident can be prevented by means of a proper tube. When a solution of fluoride of silver is decomposed by a current of chlorine gas, the chloride of silver precipitated contains fluorine, and does not blacken under the influence of the solar rays; when exposed to the light it becomes of a light brown tint, which is permanent even in sunlight. In this experiment a large portion of fluorine remains dissolved in the liquid, but it gradually decomposes the water, evolving large bubbles of oxygen gas, which appear to rise from the precipitate at the same time and not before the glass becomes attacked by the hydrofluoric acid formed.

Another mode of obtaining fluorine consists in heating with precaution a mixture of pure fluoride of calcium,

¹ I have at last obtained some fluoride of sodium chemically pure. It was prepared by Mr. J. Christian, chemist to Messrs. Jackson and Townson, of Bishopsgate Street, London, and with it I intend to continue the experiments related in this paper, when circumstances will permit me to do so.

a solution of permanganate of potash, and sulphuric acid. The gas evolved has a peculiar odour, something like that of oysters; it whitens litmus, dissolves in water, and does not attack glass, neither is the glass retort corroded in which the operation takes place. If peroxide of manganese is used, so much hydrofluoric acid is produced that, on the contrary, the whole apparatus is soon spoiled. By passing the gas obtained as above into a solution of soda I obtained a crystalline salt, which I take to be fluorate of soda, but which I have not yet examined thoroughly.

When a mixture of nitric acid, solution of permanganate of potash, and fluoride of potassium dissolved in water, is abandoned to itself for some days, a peculiar and very beautiful crystalline compound is formed: it consists of numberless small, flat, crystalline plates, of a golden bronze colour and metallic aspect, very much resembling certain varieties of mica; indeed this compound contains potassium, manganese, fluorine, and silicium, elements which we find in micas, and I look upon these crystalline plates as a sort of artificial mica.

Researches on the Relations existing between Atomic Weights, by M. J. S. STAS, Member of the Royal Academy of Belgium.

(Continued from page 208.)

Determination of the Relation between the Atomic Weights of Nitrogen, Chlorine, Sulphur, Potassium, Sodium, Silver, and Lead.—In order to ascertain the reciprocal relations between the atomic weights of these seven bodies, I have performed the synthesis of,—

1. Chloride of Silver,
 2. Sulphide of Silver,
 3. Nitrate of Silver,
 4. Nitrate of Lead,
 5. Sulphate of Lead,
- The analysis of,—
6. Chlorate of Potassa,
 7. Sulphate of Silver;
- and I have sought for the proportional number between,—
8. Silver and Chloride of Potassium,
 9. Silver and Chloride of Sodium,
 10. Silver and Chloride of Ammonium,
 11. Nitrate of Silver and Chloride of Potassium,
 12. Nitrate of Silver and Chloride of Ammonium.

By thus balancing simple bodies with simple bodies, simple bodies with compound bodies, and compound bodies with each other, I naturally arrive at results which can be controlled by each other.

Some of these determinations were undertaken many years ago; they have all been verified and completed during the last three years. I will commence the details of these researches with those which depend upon the metal silver, treating first of the preparation of pure silver, and the methods which I employed to assure myself of its purity.

Silver.—As silver has been the pivot, so to speak, of my researches, I have made every possible effort to procure this metal in a state of purity, and to make myself sure of its purity. For this purpose I have successively employed all the methods recommended to prepare pure silver. I have arrived at the certain conclusion, that all those which are capable of being executed on a large scale furnish an impure metal unless important modifications are introduced. All processes which depend upon the reduction of chloride of silver yield a metal containing copper and iron, unless, indeed, it has been redissolved three or four times successively in nitric acid, the solution, after diluting with twenty or thirty times its weight of water, being each time poured into aqueous hydrochloric acid, and the chloride of silver violently agitated in the liquid, as in the process of assaying. Experience has shown me that chloride of silver, free from copper and iron, can be obtained directly by pouring a cold solution of nitrate of silver diluted with thirty times its weight of water, into a slight excess of hydrochloric acid, washing the precipitate with cold distilled water, and then digesting the chloride, dried at the ordinary temperature, and finely powdered, in aqua regia. When well washed after this treatment, the chloride does not retain the slightest trace of either copper or iron; whilst, so long as the chloride of silver is in a curdy form, it retains in its pores, like coagulated albumen, some of the bodies which were dissolved in the liquid from which it was precipitated. Chloride of silver, however, when dried at the ordinary temperature and finely powdered, very easily yields to aqua regia foreign metals which contaminate it.

Whatever may be the purity of chloride of silver, it produces a metal which always contains silicium and iron when it is reduced by Gay-Lussac's method; that is to say, a mixture of chalk and charcoal.

The presence of these foreign matters is easily ascertained by dissolving a hundred grammes of silver in pure nitric acid in a platinum dish, and evaporating and fusing the nitrate. On dissolving the salt in cold water there is always a residue of silicic acid and sesquioxide of iron.

I have found as much as $\frac{1}{100000}$ ths of silicium in silver reduced from the chloride by Gay-Lussac's process. M. Allard, Director of the Mint at Brussels, has kindly caused to be prepared for me in the laboratories of the Mint large quantities of silver by this plan, as recommended for obtaining silver for assay. In spite of all the care taken by M. Schoonjans, whose great skill I have had occasion to notice, the silver so produced contained traces of copper, iron, and especially of silicium. Upon analysing with extreme care the silver obtained by this method, I found when operating upon 200 grammes that after one treatment it contained between $\frac{1}{100000}$ ths and $\frac{1}{100000}$ ths of impurities; after two treatments, between $\frac{1}{100000}$ ths and $\frac{1}{100000}$ ths; after three treatments, between $\frac{1}{100000}$ ths and $\frac{1}{100000}$ ths. A comparison of this silver with metal obtained by other processes has led me to absolutely the same result. Amongst the determinations of the reciprocal relation between silver and chloride of potassium, there are three which were made with silver prepared by Gay-Lussac's method, and the impurities then make themselves apparent in a very evident manner. M. Dumas has estimated at a ten thousandth part the impurities contained in the silver supplied to him by the Paris Mint.

Without confidently asserting it, I suspect that the presence of so large a quantity of silicium in the metal so prepared is due to the action which silver has upon

silicic acid. It is probable that at the temperature necessary for fusion silver reduces the silicic acid with formation of silicate and silicide of silver. Furthermore, the presence of carbon may favour the reduction of silicic acid and the formation of silicide of silver. One thing is certain, as I have frequently proved, that the vapour of silver attacks silicic acid and the silicates. White porcelain becomes coloured yellow or yellowish-brown, and increases very sensibly in weight, when there is directed upon it the vapour of silver disseminated by an oxidising flame.

Chloride of silver, purified by the above process, mixed with its own weight of pure dry carbonate of soda, containing a tenth part of pure nitrate of potash, when heated in a white unglazed porcelain crucible, with the precautions recommended by Berzelius for avoiding intumescence, yields an ingot of pure silver. This ingot, fused again with a tenth of its weight of pure nitre and borax, and then run into an ingot-mould lined with pipeclay, gives a bar of silver which retains scarcely any appreciable traces of foreign matters. This process requires great care, for when the mixture of chloride and carbonate is heated, if the temperature is raised too much at first, the mixture fuses, bubbles up, and is in danger of running over. I have, however, prepared in this way many kilogrammes of silver.

To effect with safety the reduction of chloride of silver in a white unglazed porcelain crucible, the latter should be placed inside a clay crucible. This is the way I have found most convenient for performing this operation:—I fill up the space between the two crucibles with calcined pipe-clay, powdered and mixed with 5 per cent. of fused and powdered borax. Under the influence of the heat, the borax fuses and solders the whole together. When the chloride of silver is reduced, the whole can be handled and the melted silver poured out as if it were one crucible. The great bulk which has to be heated before reaching the porcelain crucible prevents it cracking, and avoids loss of silver.

Besides this method of preparing silver, I have tried many other plans. One of them has been suggested to me by M. Liebig, who, indeed, has kindly prepared a certain quantity by this means for my researches. The process consists in reducing in the cold, by means of pure milk sugar, a pure concentrated ammoniacal solution of nitrate of silver, to which pure potash has been added until fulminating silver begins to be precipitated. After a short time a violet precipitate is formed, which is transformed into a mirror of silver, if the solution does not contain more than 10 per cent. of nitrate. If, on the contrary, it contains much more metal, the violet precipitate of silver remains. This precipitate, after being washed with water, is digested with aqueous ammonia, which removes the copper, if the silver contained any. When dried, it preserves its violet colour, and constitutes a peculiar modification of silver. Heated to 300° or 350°, the metal becomes incandescent, and then assumes its proper colour, being of a dead white. To reduce it to bars, I fuse it with a certain quantity of pure nitre and borax, and run it into an ingot-mould lined with pipe-clay.

I have prepared by this means more than three kilogrammes of pure silver, working upon a kilogramme at a time. I have always found the metal of a uniform purity, and identical with other pure silver. I say, with other pure silver, because it is not sufficient, as M. Péligot states in his memoir upon silver, to prove that the metal obtained by a certain process always has the same qualities, in order to be sure of its purity; it is

also necessary for it to be absolutely identical with pure silver prepared by other methods. Moreover, it may happen,—and this is the case in the reduction of pure chloride of silver by Gay-Lussac's process,—that the operation of reduction communicates to the metal as much impurity as has been separated by solution and precipitation.

I will now give the methods I have employed to obtain the silver with which I have controlled the metal used in my operations. I give them all, stating, however, that they are too tedious and furnish too small a quantity of silver to be used on a large scale.

The first plan consists in procuring the metal by the electrolysis of pure argentocyanide of potassium or of ammonium. I have prepared at least half a kilogramme by this plan, which is long and very costly. The deposit is made upon a surface of porcelain previously covered with a mirror of silver, by Liebig's method. For a positive electrode coke is used, obtained by heating the vapour of naphtha to redness. To obtain a nitrate of silver fit to prepare the cyanide, I dissolved in nitric acid the silver of $\frac{999}{1000}$ ths produced at the Brussels Mint. The solution was evaporated to dryness and the salt fused. After cooling it was powdered and digested in cold water, taking care not to dissolve it all, for otherwise oxide of copper would come into solution. The solution of silver was allowed to stand for three or four days, filtered through double filter-paper, then digested with an excess of oxide of silver, and allowed to remain at rest for a sufficient time. This solution is diluted with water until it only contains a thirtieth part of its weight of nitrate, and poured into pure aqueous hydrocyanic acid until cyanide is no longer precipitated. The cyanide is shaken in the liquid to finely divide it, and then washed with water acidulated with nitric acid, and finally with pure water. The cyanide is diffused in an amount of aqueous cyanic acid equal to that used in its precipitation, and then pure ammonia or potassa is added to the mixture until the cyanide is all dissolved. When undergoing electrolysis the positive pole of carbon is surrounded with cyanide of silver, contained in a linen bag, purified by means of hydrochloric acid. I thus return silver to the liquid as fast as it is removed by electrolysis. I have been unable to find any foreign body in this silver after it has been fused in an unglazed porcelain crucible with a mixture of purified nitre and borax.

I have likewise made use, to prepare pure silver, of the reaction between finely-divided phosphorus upon a one-per-cent. solution of nitrate of silver. This action is very slow, but the metal, after having remained for a long time in an excess of solution of silver, and then being digested in ammoniacal water, yields, after fusion with purified nitre and borax, silver absolutely pure. By this reaction I obtained the first pure silver that I ever possessed.

Finally, I have prepared silver by the action of heat upon the acetate, which had been re-crystallised at least ten times. This metal, after fusion with nitre and borax, has appeared not so pure as the preceding.

The process recently described by M. Cavanna gives a very pure metal, but it is impracticable on the large scale. M. Péligot has already made the same remark.

I have discovered a very simple plan for ascertaining the purity of silver. The pure metal remains melted in the air at a sufficiently high temperature to volatilise it without being covered by any scum or coloration, and without giving a coloured vapour. Silver containing no more than the five hundred-thousandth part of iron,

copper, or silicium becomes covered with a very strong and mobile scum when it is fused before a blow-pipe, fed with a mixture of illuminating gas or hydrogen and an excess of air. Silver containing scarcely appreciable traces of copper when volatilising in an oxidising flame always gives a coloured flame. This assay may be performed on charcoal or white-burned pipe-clay, or on porcelain, by means of a gas blow-pipe or a simple eolipyle. The scoria derived from the impurities in the metal always forms upon the surface of the flattened spheroid caused by the fusion. After cooling, the foreign matter is found adhering to the silver near the point of contact of the metal with the support.

All the specimens of assay silver that I have been able to procure have yielded scoria more or less evident. This amount of impurity, however, in no way interferes with the results of the assays made at the Mint.

I have already said that I have ascertained by direct analysis the quantity and quality of the foreign matters present in silver prepared by Gay-Lussac's process, as described. As this method necessitates the sacrifice of 200 grammes of silver in each assay, I have replaced it by the wet process of assay, as used in Mints, taking the precaution to increase tenfold the quantity of metal experimented upon. For this purpose I have devised an apparatus, of which a drawing is given in my Memoir. It consists of two distinct parts,—a large glass reservoir, filled with a normal saline solution, and a large pipette, terminated at the upper part by a tube of about five or six millimètres internal diameter, to which is cemented a stop-cock, and at the lower part by a tube of two millimètres internal diameter. This pipette is replenished from below, and is fixed in a case filled with water kept at a uniform temperature. Filled twice up to a mark scratched on the upper tube, it contains at 10°2 an amount of common salt sufficient to precipitate ten grammes of the purest silver I have been able to procure. I will not now enter into the details of these experiments. I will give an account of all the precautions which I have taken to ensure the almost absolute accuracy of the results, when speaking of the proportional relation between silver and chloride of potassium, sodium, &c.

Before leaving this subject, I must still mention the form in which I have employed the silver used in my experiments. All the metal has been fused and cast in an ingot-mould, lined with white pipe-clay. To detach the pipe-clay, the surface of the bars is rubbed with sharp white sand. They are then heated to dull redness and covered over with caustic potassa, which is kept in a fused state for at least a quarter of an hour. The adherent pipe-clay being in this manner attacked, the bars are suddenly plunged into water. The silicate formed on the surface being thus detached, the bars, after a second scrubbing with sharp sand, are fit for use. These bars, before being employed, are treated with boiling hydrochloric acid, washed first in cold aqueous ammonia, then in pure water, and finally heated to redness on plates of pure silver.

My experiments have rendered it necessary for the silver to be in the form of small lumps, from two to twenty-five grammes in weight, in the form of sheet, and in a certain state of division to make up weights previously calculated. I obtained the small lumps by cutting the ingots with a chisel on an anvil of polished cast steel. The turnings and filings obtained from the ingots by means of a lathe and file have furnished the finely-divided silver. To separate the iron adhering to the silver when cut with the chisel, lathe, or file, I digest these different forms of the metal in a close vessel for

twenty-four hours, and at a temperature of 60° to 80° , first with strong hydrochloric acid, and then with pure ammonia. The silver is finally washed with absolutely pure water, heated to redness on a plate of pure silver, and immediately put into bottles with well-fitting stoppers.

Having found that the silver, after having been rolled at the excellent mills belonging to our Mint, contained iron, which was absent before rolling, I took the precaution to have all the silver which I required in the form of sheet rolled between two plates of pure silver. It is only at the expense of the surfaces of the two plates which touch the cylinders of the mill that I have been enabled to protect the surface of the inner plate from contamination with all foreign metal. The plates of silver employed in the synthesis of the sulphide and in some of the syntheses of the chloride of silver were thus obtained. The laminated silver was likewise heated to redness in the air, and enclosed whilst very warm in a well-stoppered bottle.

I thought for a long time that, after having taken all the precautions detailed above, I had succeeded in obtaining silver absolutely pure. An experiment has, however, undeceived me. When performing the synthesis of nitrate of silver upon about 400 grammes of this metal, I have still found the presence of some traces of silicium, not, however, more than 2 parts in 100,000.

(To be continued.)

Analytical Notes, by M. H. ROSE.

Precipitation of Mercury in the State of Protochloride by Phosphorous Acid.—The best method for estimating mercury is to precipitate it in the state of protochloride by phosphorous acid. When the liquid contains free hydrochloric acid the temperature may be raised to 60° without the protochloride of mercury being reduced to the metallic state by phosphorous acid. The precipitated protochloride is not immediately formed in very weak liquids; it is necessary to leave the mixture undisturbed for twelve hours. The chloride deposits itself readily, especially when the liquid is sufficiently acid.

The precipitate is to be collected on a filter, washed with cold, or even hot water, and dried at 100° . This process is very applicable to cases where the liquid contains much nitric acid. Only the solution must then be diluted with a sufficient quantity of water.

The mercury can be easily separated by hydrochloric acid and phosphorous acid from copper, cadmium, zinc, and even bismuth, antimony, and arsenic. When the liquid contains bismuth a large excess of hydrochloric acid must be added to prevent the precipitation of oxichloride of bismuth. The mercury being separated in the state of protochloride, the bismuth is precipitated in the filtered liquid as oxichloride, then reduced to the metallic state by fusion with cyanide of potassium.

If the liquid contain antimony, this body is to be retained in solution with tartaric acid, which does not hinder the precipitation of the mercurial chloride.

Separation of Mercury and Lead.—The preceding method is not applicable to the separation of mercury and lead. A portion of the lead is precipitated in the state of chloride with the protochloride of mercury. A better plan for analysing a mixture of the salts of these two metals is to add sulphuric acid, and then alcohol forming about $\frac{1}{3}$ th of the volume of the liquid. If this does not contain sufficient hydrochloric acid, and if the proportion of sulphuric acid is insufficient, yellow sub-

sulphate of mercury may be precipitated, which is avoided by the addition of sulphuric acid. The sulphate of lead requires washing with weak alcohol acidulated with sulphuric acid.

Separation of Mercury and Silver.—Add a sufficient quantity of hydrochloric acid to the diluted solution. After the deposition of chloride of silver, decant the supernatant liquid; then heat the chloride precipitate with a small quantity of nitric acid, add some water and a few drops of hydrochloric acid, and then filter. Precipitate the mercury from the filtered liquid by phosphorous acid.

Reduction of Mercuric Chloride by Alkaline Formiates.—M. de Bonsdorff proposed to precipitate mercury as protochloride by alkaline formiates. This method may lead to completely erroneous results, as alkaline formiates do not invariably reduce bichloride of mercury. The affinity of mercuric chloride for alkaline chlorides is so great that when these bodies are present the ordinary reactions of mercury are not produced. When a liquid contains much hydrochloric acid, an alkali does not precipitate oxide of mercury from it. Sulphuric and nitric acids have the same effect. Such a mercuric solution, containing a large excess of potassa, is not precipitated by sulphide of ammonium unless the base has been previously supersaturated with an acid.

The same remark applies to the chlorides of other precious metals, particularly to chloride of gold. In presence of a considerable excess of hydrochloric acid or alkaline chlorides, a small quantity of salt of protoxide of iron or oxalic acid does not suffice to reduce chloride of gold. A large excess of the re-agent is necessary.

Estimation of Mercury in its Solid Combinations by Distillation.—In estimating mercury by distillation it is necessary, especially if the metal is in the state of chloride or sulphide, to take certain precautions, without which a portion of the sulphide or chloride would volatilise without decomposition. The operation is conducted by introducing into a glass tube capable of resisting fusion, closed at one end, and measuring from 35 to 50 centimètres in length, a column of bicarbonate of soda, then one of quick lime, and then a well blended mixture of a mercurial salt and quick lime, and finally a column of quick lime. The open end of the tube is drawn out and bent round so as to enter a small flask containing water. The tube is heated as if for an organic analysis, commencing at the open end and finishing with the bicarbonate of soda. The operation ended, cut the bent end of the tube. Collect all the mercury in the flask, dry with paper, and afterwards over sulphuric acid, and then weigh it.

There is no need to replace the quick lime by hydrate of lime. That would occasion all the inconvenience of an analysis of a sulphuretted combination of mercury. The water, acting on the sulphide of calcium, would form sulphuretted hydrogen, which, by dissolving in the water of the receiver, would in time transform a portion of the reduced mercury into sulphide. It is even advisable in this case to replace the bicarbonate of soda by carbonate of magnesia.

Combinations containing iodide of mercury are not entirely decomposed when treated as above. Biniodide and protoiodide are condensed in the extremity of the tube simultaneously with the metallic mercury.

To analyse these combinations recourse must be had to metallic copper, the operation being similar to that with quick lime.—*Poggendorff's Annalen.*

On Rubidium and Cesium,¹ by M. BUNSEN.

IN addition to the facts which we have already published on the subject of these two metals, discovered by M. Bunsen, by means of spectrum analysis, we add the following:—

The equivalent of rubidium is 85.36 ($H = 1$), more than double that of potassium; metallic rubidium is even more electro-positive than potassium,—it amalgamates easily and decomposes water in the cold.

The hydrate of rubidium, $RbO.HO + Aq$, is soluble in all proportions in water and alcohol. When heated it fuses in its water of crystallisation, becoming reduced to the state of $RbO.HO$, which is fusible at a higher temperature without losing weight. It acts like caustic potash, attracting water and carbonic acid from the air, and dissolves in water with disengagement of heat.

The carbonate, $RbO.CO_2 + Aq$, forms ill-defined crystals, of strong alkaline reaction, fusible by heat in their water of crystallisation, and becoming anhydrous. This salt is fusible, deliquescent, and attracting from the air a second equivalent of carbonic acid. The aqueous solution saponifies the skin exactly like carbonate of potash.

The bicarbonate, $RbO.CO_2 + HO$, forms brilliant prisms, unalterable in the air, having a slight alkaline reaction, and a saline taste not at all caustic.

The nitrate, $RbO.NO_3$, does not crystallise in rhombohedral prisms like saltpetre, but in prisms with a hexagonal base, which is a second form of nitrate of potash. It dissolves in 5 parts of water at $0^\circ C$, and in 2.3 parts of water at $10^\circ C$.

The sulphate, $RbO.SO_3$, is isomorphous with that of potash. At $7^\circ C$ it dissolves in 2.4 times its weight of water, and is, consequently, more soluble than sulphate of potash, which requires 10.4 times its weight of water to dissolve it. With sulphate of magnesia it gives a beautiful octohedral salt, and with sulphate of cobalt another double salt, in fine crystals, isomorphous with $CoO.SO_3 + KO.SO_3 + 6HO$.

The bisulphate of rubidium can be fused at a moderate temperature without decomposition, but at a higher temperature it is reduced to the neutral salt.

The chloride of rubidium is cubic, but crystallises with difficulty. It is fusible and volatilisable at the extremity of a platinum wire. From 1° to $7^\circ C$ it dissolves in 1.2 to 1.3 parts of water; KCl requires 3.4.

The double chloride of platinum and rubidium, $RbCl.PtCl_2$, is a crystalline powder composed of microscopic octohedra. It only differs from the double chloride of platinum and potassium by its less solubility; it only dissolves, indeed, in 1.8 times its weight of boiling water, whereas the potassium salt only requires 1.9 times its weight.

Cesium (from *cæsius*, sky-blue, on account of the colour of the ray which it produces in the spectrum). The double chloride which it forms with platinum is still less soluble than that of rubidium. Its equivalent ranks by the side of those of iodine and gold, 128.4, and is, consequently, one of the highest.

The hydrate of cesium, $CsO.HO + Aq$, is deliquescent. When heated it loses an equivalent of water, attacks platinum, volatilises in a spirit-flame, and easily dissolves in alcohol.

The carbonate, $CsO.CO_2 + Aq$, crystallises badly at $19^\circ C$. It dissolves in 9 times, and at $78.4^\circ C$ in 5 times its weight of absolute alcohol. It is very caustic, liquefies

in the air, and is transformed into bicarbonate. It is soluble in all proportions in hot water.

The bicarbonate crystallises in brilliant prisms.

The nitrate is anhydrous, like that of potash, with which it is isomorphous. It has the taste of saltpetre, as also has the nitrate of rubidium.

The sulphate of cesium is also anhydrous, and crystallises badly. At $2^\circ C$, 1 part of this salt requires 0.63 parts of water to dissolve it. It forms double salts with the magnesian sulphates, and these double salts are isomorphous with those formed with the same sulphates and the sulphates of potash and ammonia. With sulphate of alumina the sulphate of cesium forms a very brilliant octohedral alum.

The chloride crystallises in cubes, but it is distinguished from those of potassium and rubidium by being deliquescent, like the chloride of lithium. It is fusible and volatile at a comparatively moderate temperature.

Cesium is less abundant than rubidium, which, however it generally accompanies; the richest source is the mineral water of Durckheim. 10 kilogrammes of this water contain 2 milligrammes of chloride of cesium; and it has been from the residue of the evaporation of this water that I have prepared it, by precipitating it with bichloride of platinum, and submitting the alkaline chloroplatinate to successive exhaustions with boiling water until only the chloroplatinate of cesium was left, this, as we have seen, being the most insoluble of all, and possessing also the highest equivalent.

The lepidolites contain only traces of cesium, but, on the contrary, they are rich in rubidium, and it is from these that M. Bunsen has prepared the latter. The lepidolite from Rosena (Moravia) contains two-thousandths of its weight of oxide of rubidium, and that from Saxony appears still richer. Probably all the saline mineral waters contain it; that of Durckheim contains two-millionths, and the mother-liquor about four hundred-thousandths of chloride of rubidium. Commercial potash, however, does not always contain it.

On the Preparation of Nitrate and Nitrite of Ethyl,
by M. CAREY LEA.

Nitrate of Ethyl.—The tendency of alcohol to decompose nitric acid is so great that while we have any number of processes for obtaining nitrite of ethyl, Millon's is the only one known for forming the nitrate. But Millon's process fails much oftener than it succeeds (such, at least, has been my experience), in consequence of the proportion of urea directed to be used being much too small.

Millon's process, as quoted in Kolbe's "Organische Chemie," directs to distill equal weights of alcohol and of colourless nitric acid, specific gravity 1.401. Not to operate upon larger quantities than 120 to 150 grammes, and to add a little urea to the above quantity, at most ("höchstens") 2 grammes of urea.

Conducted as above, the operation succeeded with me but once out of four or five times. But by using a large quantity of urea, three or four times as much, or even more, success invariably follows, and there results a great saving of urea, because when the process fails, the materials, urea included, are entirely lost, whereas when conducted as just described, very little urea is consumed. It is only necessary to add fresh acid and alcohol, after the first proportion has been distilled to about one-fifth, and the process may be repeated almost indefinitely, with the occasional addition of a little urea to keep up

¹ *Annal. der Physik und Chem.*, t. cxlii., p. 337.

the proportion. The product in the second and subsequent operations is much larger than in the first.

Nor have I found it necessary to operate on the small quantities above mentioned, but have habitually used quantities amounting to 400 to 500 grammes, and should not hesitate to employ still larger ones. It is, however, more convenient to use the above quantity, and replace the material as fast as exhausted.

The facility with which nitrate of ethyl can be obtained by the above process must, I think, give it a decided advantage over the iodide of ethyl for the preparation of the ethyl bases, in the manner which I have recently described.¹ The lower equivalent of nitric acid as compared with iodine is a matter of considerable importance; 100 parts of iodine are capable of holding in combination something less than 23 of ethyl, whereas 100 parts of nitric acid combine with over 53 of ethyl,—a material point, as the iodine on the one hand and the nitric acid on the other are merely the vehicles for bringing about the ethyl substitution. In operations in pressure-tubes, where space is valuable, this is an important consideration; in an economical point of view also the advantage appears to be greatly on the side of the nitrate of ethyl.

Nitrite of Ethyl.—The action of nitric acid on alcohol in the preparation of nitrite of ethyl may be conveniently moderated by protosulphate of iron, and the nitric acid reduced by that agent instead of at the expense of part of the alcohol. The proportions which I have used are, nitric acid, specific gravity 1.37, 90 cubic centimetres; alcohol, of 90 per cent., 150 cubic centimetres; ferrous sulphate, 45 grammes. The product is very large; the distillate, on being shaken up with water, yields more than half its bulk of nitrite of ethyl. The latter is not perfectly free from aldehyde, but more so than that obtained by some other processes. The action is perfectly quiet to the last, and the distillation may be carried on rapidly.—*American Journal of Science*, No. 95.

TECHNICAL CHEMISTRY.

On the Artificial Colouring Matters derived from Aniline,
by M. E. KOPP.

(Continued from page 210.)

Believing in the identity of fuchsine and azaleine, MM. Persoz, de Luynes, and Salvétat endeavoured to separate the pure colouring matter from them in the following way:—They mixed each of the products with six or seven times its volume of alcohol, and then filtered. To each alcoholic solution they added pure ammonia as long as any precipitate was formed, and the liquor became colourless or of a light amber. They then filtered again to separate the precipitate, which in the case of fuchsine consisted of stannic oxide, and, in the case of azaleine, of resinous matter. The ammoniacal solutions contained the whole of the colouring matter. These were saturated with acetic acid, and then a saturated solution of bichromate of potash was added, which produced a red precipitate. This was collected and carefully washed. As long as the washings contain saline matters they run away uncoloured, except by the bichromate; but as soon as the saline matter is gone, the precipitate begins to dissolve. If, now, the washing be made with hot water, a solution is obtained charged with the colouring matter,

which is the same, whatever may have been its origin. Baryta, or lime, may be substituted for ammonia in the above experiment.

The authors of this report, without denying that the colouring matter may at times play the part of a base, contend that it quite as often, and perhaps oftener, plays the part of an acid. In fact, under the influence of acids the fuchsine, or rather fuchsic acid, always dyes, for under these circumstances it is free. But fuchsic acid, combined with powerful bases, such as ammonia, potash, and soda, forms colourless compounds, which only dye when an acid is present to displace the base and fit it to unite with the fabrics. Fuchsic acid, indeed, behaves under these circumstances exactly like carthamic acid.

The aqueous solution of the colouring matter prepared in the method before described behaves with re-agents in the following manner:—Caustic alkalies and the alkaline carbonates remove without destroying the colour, for it re-appears on the addition of an acid. Chloride of platinum at first produces only a cloudiness in the solution, but, after a time, a purple precipitate forms. Chloride of gold gives a deep purple precipitate immediately. Sulphocyanide of potassium, after some time, gives a precipitate like purple of Cassius. Stannous chloride in the cold almost decolorises the solution; warm, it gives a colour like wine lees, and a few drops of acetate of soda precipitates a rose-coloured lake. Stannic chloride in the cold modifies the substance, altering the colour, the change being more pronounced when a warm solution is used, the precipitate lake being of a dirty rose colour. Manganate and permanganate of potash produce no precipitate, but give a fawn colour to the solution. Hyposulphite of soda gives a violet shade to the colour. Chlorine at first blues and then decolorises the solution. Chloride of lime partially decolorises it in the cold, and completely when warm, the stannous chloride no longer reproducing the colour. Saturated solutions of alkaline salts precipitate the liquor, as soap is precipitated by some saline matters. Sulphurous acid decolorises the solution, but an oxidising agent carefully employed restores the colour.

The purified colouring matter from fuchsine contains no chlorine, and, whatever the origin of the red matter, it always contains about 70 per cent. of carbon and 13 per cent. of nitrogen.

The distinguishing characters of the red colouring matter, fuchsine, and the violet colouring matter, indisine, may be summed up as follows:—

Fuchsine is soluble in ammonia; indisine is not. Fuchsine forms a yellow solution in sulphuric acid; indisine gives a blue. Fuchsine is decolorised by sulphurous acid; indisine is not changed. Lastly, indisine, being the result of the oxidation of aniline, which is one of the derivatives of indigo, presents so many analogies with the last body, that, forgetting for the moment that indisine is a violet colour, it might be taken for indigo when witnessing in it all the phenomena of oxidation and reduction so easily effected with indigo.

M. Kopp objects to the use of bichromate of potash in the process for the purification of fuchsine and azaleine proposed by MM. Persoz, de Luynes and Salvétat, and thinks it possible that the action of this body may produce the identity which they seek to establish. Is it not possible, he asks, that the colouring matters not identical, yet extremely alike in composition and properties, may, under the influence of such an agent as bichromate of potash, be converted into one and the same compound, just as starch, dextrine, and various

¹ CHEMICAL NEWS, August 17, 1861, No. 89, Vol. IV. p. 38.

kinds of sugar are converted into oxalic acid by the action of an oxidiser? M. Kopp, therefore, prefers a method of purification in which only entirely neutral bodies, such as sulphide of carbon, benzine, and alcohol, are made use of. A process of this kind has been invented by M. Schneider for the purification of fuchsine and azaleine. To purify azaleine, M. Schneider first rubs together in a mortar, for about ten minutes, three parts of the rough product and three or four parts of cold water. The mixture is then allowed to stand for an hour, and then the supernatant liquor is poured away. This washing is repeated at least six times, the object being to get completely rid of the salts of mercury and aniline, more or less of which are always present. A little of the colouring matter is lost in this way, but not much. The azaleine must next be dried. It is then rubbed with about an equal quantity of sulphide of carbon for ten minutes. At first the colouring matter is very sticky and difficult to rub, but by degrees it becomes almost pulverulent, and then yields nothing more to the sulphide, which may be poured away. This operation is repeated several times. The mixture may then be thrown on a filter to drain. What remains on the filter is dried in the air, reduced to an impalpable powder, and then treated with pure benzole seven or eight times, or as long as the benzole becomes coloured. The powder is then dried again in the air. Lastly, 40 grammes of this dry impalpable powder are treated with 400 grammes of alcohol. A quarter of the alcohol is added at a time, and, after stirring together for about ten minutes, the solution is poured off into a large bottle, and another quarter of the alcohol is added, and so on, to dissolve the whole of the colouring matter. 440 grammes of cold distilled water is now added, the mixture well shaken, and then allowed to stand until the following day. All the foreign matters and some of the colouring matter are precipitated by the distilled water. After filtering, the solution of the now perfectly pure colouring matter is evaporated on a water-bath to about a sixth of its bulk, and then allowed to cool. The mother liquor is decanted on the following day, and at the bottom of the dish will be found a crystalline pellicle, scattered over with brilliant scales. The whole is dried, in the air for a couple of days, and finally on a water-bath.

The process for purification of fuchsine differs but little from the above. Fuchsine is much more soluble in water than azaleine; to avoid loss, therefore, it is necessary to use iced water in the first washing. The mass is then exhausted with alcohol, which leaves 30 or 40 per cent. of insoluble residue. The alcoholic solution is then evaporated or distilled to dryness, and the dry product treated as in the case of azaleine.

Passing from the red and violet-red colouring matters, M. Kopp proceeds to notice the reports of MM. Wilm and Scheurer-Kestner on aniline violet. This is obtained by the action of bichromate of potash (Perkins) or peroxide of manganese (Kaye) on a salt of aniline, or, preferably, by adding hydrochlorate of aniline to a solution of chloride of lime (Beale and Kirkham). The violet precipitate in these cases is accompanied by a brown colouring matter and a resinous body. The brown matter is the most abundant product, and the greater part of it remains in solution in the mother liquor; it dyes silk and wool a maroon colour without the intervention of a mordant; it is easily separated from the violet in consequence of its solubility in alkalies, in which the violet matter is insoluble.

The resinous body is insoluble in water, weak alcohol, and acetic acid, but soluble in absolute alcohol, sulphide

of carbon, ether, and benzole. As the violet matter is insoluble in the three last named, they may be used to separate the resinous matter from a mixture of the two. Aniline violet itself is soluble in boiling water, alcohol, wood-spirit, acetone, aniline, and acetic, hydrochloric, sulphuric, and tartaric acids. Water, and especially when charged with neutral saline matters, caustic alkalies, or even metallic salts, precipitates it from these solutions. In the latter cases, the colouring does not combine with the metallic oxides to form lakes.

The alcoholic violet solution is decolorised by chlorine water, but the colour is restored by sulphurous acid; sulphurous acid and the sulphites do not decolorise it; but the colour is discharged by the combined action of zinc and sulphurous acid. Chlorine now restores the colour, but with some alteration; it is redder and no longer possesses the violet shade.

Heated on a plate of metal, dry aniline violet appears to volatilise and give red vapours; but crystals cannot be obtained by sublimation either *in vacuo* or under the ordinary pressure of the atmosphere. It seems to decompose into aniline (which carries away with it some of the violet matter unchanged) and a good deal of carbon. A solution of the pure violet matter in strong acetic acid yields prismatic crystals, which, when dried, have a more brilliant green shade than the dried amorphous mass from the evaporation of the alcoholic solution.

The analysis of aniline violet by Wilm yielded results from which he calculated its formula to be $C_{20}H_{17}N_3O_2$; and the reaction which takes place in its formation he represents as

The analyses of Scheurer-Kestner, however, gave results which led to the formula $C_{30}H_{14}N_2O_2$, according to which the reaction will be

On some Applications of Ebonite, or Hard India-Rubber,¹ by H. A. SILVER.

THE material known as hard india-rubber, vulcanite, horn-rubber, or, in its most perfect condition, as ebonite, was first obtained by Hancock, although its discovery was also effected by the independent researches of Goodyear. Ebonite consists of india-rubber, vulcanised with sulphur at a high temperature, which is continued for several hours. As in the case of caoutchouc, or pure india-rubber, the applications of this *matériel* were, until lately, extremely limited. It is principally met with in the form of combs, paper-knives, and penholders; but the peculiar properties it possessed render it available for far more important uses. Its acoustic qualities have been utilised in the construction of stethoscopes, and render it well adapted for ear-trumpets and for flutes, and several other wind instruments. Like horn or ebony it may be turned in a lathe, although in practice it is found preferable to produce it in moulds of any desired form. It is a most powerful, probably the most powerful negative ideo-electric; and, from not being liable to fracture, it advantageously replaces the glass plates of electrical machines. From this fact, and from its possessing no hygroscopic attraction for moisture, it may be inferred that it is also an excellent insulator of electricity. Apart from its application in the form of insulators for overground wires, it is found most useful

¹ Abridged from a Paper read before the British Association.

We concur in Mr. Galloway's opinion of the plan adopted by Fresenius. There can be no doubt about its being tedious and difficult. The objection to tabular statements of analytical plans entertained by the great German analyst, seems almost morbid. Whether they appear as tables or not, analytical operations can only be represented in tabular statements. Those given by Fresenius are merely spread over some two or three pages, somewhat vaguely, instead of being concentrated in a systematic and intelligible form on one page only. Fresenius' plan is less costly to print, but, at the same time, more difficult to understand. One can scarcely work through a few pages of his "System of Instruction in Qualitative Analysis" without meeting with such delightfully complicated directions as this,—"Test for cobalt and nickel, as directed, § 192, 1, b, β , $\beta\beta$, (149)."

Mr. Galloway characterises the ordinary system as difficult as well as defective; he says, "It is so difficult, that those who employ it generally teach one thing, useless in itself, in order that they may teach another; they teach the student first to look for one acid and one base—a limitation which is not adopted in actual practice—solely for the purpose of rendering the course in which they have [?] he has] to look for all the bases and acids less difficult." We do not think it quite useless for the student to be able to detect one acid and one base; the principle of progressive exercises is one universally adopted, even by Mr. Galloway himself, who recommends the student to examine each group by itself—why not, then, each individual member?

Our author proceeds thus:—"In the plan I have adopted, the properties of the different members of each group are contrasted by placing them in parallel columns; the advantage of this is, that the student, after he has performed the experiments, is able himself to devise methods for the detection and separation of the different members; it places him, in fact, in the position of a judge who has to decide some cause after having heard all the pleadings." The plan here referred to consists merely of a further development of the plan of tabular statements. Mr. Galloway speaks of the reason and judgment exercised by the student using these tables. We think that the behaviour of the various bases and acids ought to be ascertained in a less narrow way, as pointed out above, and that the tables of properties are not unlikely to assist in making the student an "analytical machine." A careful selection of reactions ought to be presented to the beginner under each base and acid, while the analytical schemes subsequently given, ought not to do much more than suggest how the general and special tests may be successfully applied in the detection of the substances met with in analysis. The tables showing the reactions of the various bases and acids are very full, and present, without doubt, much information in a small compass, but they are not peculiar to the present Manual, and have been largely employed in other works.

Those features of his Manual to which Mr. Galloway specially directs attention, do certainly enable a student to acquire the power of performing analyses more rapidly and more easily than the ordinary system does: whether this power rests upon as secure a foundation of knowledge, is a matter of doubt.

The present edition is brought down in every important particular to the state of analytical knowledge at the present time. The photo-chemical method of Cartmell and the spectrum experiments of Bunsen will be found described very clearly and fully. Many of the special tests recently introduced into the laboratory, such as the excellent method of separating cobalt and nickel by means of nitrite of potash, will be here found in their proper places. We do not find, however, any reference to the use of biniodide of lead as an oxidizing reagent, although it is found extremely useful, in conjunction with nitric acid, for detecting traces of manganese carried down in the

ammonia precipitate (Group iii.), and for ascertaining the presence of chromium in the same precipitate. In the latter case a small portion of the precipitate is boiled with biniodide of lead in the presence of a solution of potash, chromate of potash being thus formed. We have not been able in actual practice to carry out quite successfully Mr. Galloway's table for the analysis of Group iii.; we do not think that much reliance should be placed upon the solubility, when iron is present, of sesquioxide of chromium in cold soda-solution taken in connection with its subsequent precipitation on boiling.

With a few trifling exceptions, such as those we have noticed, the book is a thoroughly good Manual of Analysis, and can be mastered in a short time. It is highly appreciated in several large schools, and is found of very great use by Medical students.

Report of the Committee on the Decay of the Stone of the New Palace at Westminster.

THIRD NOTION.

IMMEDIATELY following the examination of Mr. Szerelmey, the Committee were engaged in taking the evidence of Mr. Frederick Ransome, of Ipswich. It will be remembered that these gentlemen have urged rival claims in regard to the application of their respective processes to the Palace at Westminster; they were the first to undertake experiments in connection with the preservation of the stone actually forming part of the building; the results arrived at by them were capable of closer scrutiny and of more minute inquiry, and assumed, therefore, on this account a greater importance as compared with other and later suggestions which had not yet to the same extent been submitted to experimental trial.

During the month of August, 1859, the processes of Mr. Szerelmey and Mr. F. Ransome appear to have been first brought into direct competitive examination. At that period Sir Charles Barry sanctioned the treatment of the two bays on the river front, which were to be prepared each as an illustration of the capabilities of the process, with the view afterwards of applying on a larger scale that which should prove more successful in the preliminary trial. These specimens of protective workmanship have been reported on at the instance of the Government conjointly by Sir Roderick Murchison and Professor Faraday; been again inspected by the present Committee, and so frequently have formed a topic of discussion in the public journals, that it is needless now to remark more than the simple circumstance that the peculiar whitish appearance of Mr. Ransome's bay has been objected to, and that slight indications of efflorescence have made themselves apparent.

A still earlier application to the Houses of Parliament of the then recently patented process of Mr. Ransome dates as far back as the autumn of 1856, but the examples of that early period are not accounted by the inventor as successfully representing the capabilities of his mode of treatment from their having been the very first outdoor experiments of the kind, and executed without a full knowledge of all the requirements. The earliest, and at the same time satisfactory, example of the process is afforded by the Baptist Chapel, Bloomsbury, which was coated in the year 1858. The whole front of the chapel is of Caen stone, which, prior to the application of the process, is said to have been in a state of very rapid decay. Mr. Ransome refers particularly to the treatment of the Bath stone façade of the Royal Mews at Buckingham Palace as being the most successful example in London, but this having been executed so recently as 1860, cannot, we think, yet be considered as exhibiting a satisfactory indication of the value of his process. The Custom-house at Greenock, built of sandstone, is stated to be in every way a fair illustration. This was coated in 1859.

In regard to the nature of the process employed by Mr.

Ransome, we are in possession of the full particulars made known in the patent specification, and every information has most promptly been furnished by the inventor as to the materials employed and the mode of manipulation. The Committee appear also to have been assisted in their inquiries with reference to the solution of a problem of considerable experimental difficulty, viz., the determination of the depth to which the chemical preparation actually penetrates the substance of the stone. This point has not yet been properly ascertained, and we propose later to take an opportunity of resuming the discussion on this question, which will be more appropriately introduced after the nature of the materials themselves has been announced.

The object of Mr. Ransome's process is to deposit by precipitation within the pores of the stone an insoluble silicate of lime; this compound consisting wholly of imperishable mineral constituents, is intended to afford protection to the stone by rendering it less absorbent for water, and by preserving it likewise from the influence of the atmosphere. Such insoluble compound is formed by double decomposition between silicate of soda and chloride of calcium, applied as solutions and in this order to the surface of the stone. It will be seen, therefore, that besides the insoluble silicate of lime, an equivalent proportion of chloride of sodium must always be produced, and it appears probable that to this second product must partially be ascribed the tendency already referred to of causing an efflorescence on the outside faces of the stone. It was found to be possible to construct a block or kind of artificial stone from powdered materials, moistened alternately with these two solutions, and the property possessed by such blocks of resisting for a time the action of water, was conclusively demonstrated by the inventor. So great indeed is the degree of protective action communicated by the presence of the calcareous silicate, that limestone which has been thoroughly coated with this substance, is said to remain unacted upon when immersed in weak acids. In proceeding to the manufacture of "artificial stone," modes of operating have been resorted to for the formation of a compact mass, which are no longer similarly applicable to the walls of the Houses of Parliament; thus Mr. Ransome describes the interesting results obtained by exposing to heat the mixture of materials above referred to, whereby varieties of even greater insolubility were produced.

The objection which does not appear to have been conclusively answered in regard to this process, has reference to the impracticability of producing by double decomposition, especially when one of the secondary products is soluble in water, a condition of surface which is totally unaffected by the rain or moisture of the atmosphere; thus it would appear difficult so thoroughly to close the pores of the stone, as to prevent the extrusion of the chloride of sodium by water coming in contact with the face of the block. If removed, cavities, gradually widening, must be formed in consequence, which would permit of a subsequent and progressively increasing action upon the stone, due to the admission of the atmosphere. Moreover, the silicate of lime itself is a precipitate, somewhat gelatinous in nature, and occupies more bulk when moist, or at the time of its formation, than when it eventually becomes dry and sinks in the pores of the stone.

NOTICES OF PATENTS.

391. *Manufacture of Paper from a Pulp obtained from Wood.* E. H. BARRÉ and C. M. J. BLONDÉL. Nantes, France. Dated February 16, 1861.

This invention relates to an improved method of effecting the disintegration of wood for the purpose of obtaining therefrom ligneous fibres suitable for the manufacture of

coarse paper. The patentees employ as the agent for facilitating the separation of the fibres nitric acid; but inasmuch as the strong acid would be liable to act too energetically upon the substance of the wood, it is preferred first to saturate the shavings or sawdust with water, and then to proceed to the treatment with nitric acid. In this manner the structure of the wood is softened, so that little mechanical aid is required to reduce it to the condition of supple ligneous fibre, and after a thorough washing, the material is ready for bleaching and general treatment like any ordinary paper pulp. But, with a view of economising the nitric acid, and at the same time obviating the inconvenience arising from the corrosive action of the acid in the wood upon the metal of the crushing rollers, it is preferred to convert the free nitric acid into nitrate of soda by adding a sufficient quantity of carbonate of soda immediately after the acid treatment. By evaporating the washing liquors a crude nitrate may be recovered, which, although containing organic matter and other impurities, will serve admirably for the preparation of new supplies of nitric acid by distillation with oil of vitriol. As the result of the oxidation by nitric acid of the resinous matters in the wood, a certain quantity of carbazotic acid is generated, which, on the addition of alkali, produces a dark brown colour; the pulp loses much of this simply by squeezing in a press, and afterwards can be thoroughly bleached by washing and the treatment with chlorine. As a means of expediting the course of these operations, the inventors prefer to employ heat in some of the processes, but several hours' crushing are requisite for the production of the finer kinds of pulp.

The addition of carbonate of soda to the woody matters while the acid is yet retained in their structural cavities, would serve an important end, which is not alluded to in the specification, although several matters of inferior moment are deemed by the patentees worthy of the full scientific explanation therein given. The principle of subjecting a vegetable structure to the alternate action of free acid and an alkaline carbonate was one originally proposed, and very successfully carried out, in connection with the manufacture of linen from flax. It was found that the carbonic acid gas liberated as the result of this action was capable of exerting a considerable amount of disruptive force, which was useful in tearing open the structure, and in facilitating the subsequent mechanical treatment for the separation of the fibres. The mode of proceeding now described differs only in the detail of substituting an expensive acid for that formerly employed.

408. *Preparation of Alkaline and Earthy Cyanides.* W. CLARK, Chancery Lane, London. A communication. Dated February 19, 1861.

This patent refers to the production from ammonia of alkaline and earthy cyanides and ferrocyanides. The process of conversion is effected by passing a current of ammoniacal gas over a mixture of a carbonate of one of these bases with charcoal, pitch, tar, or other reducing agent, heated to dull redness in any suitable furnace. The employment of crude soda and potash, which contain a certain quantity of caustic alkali in addition to the carbonate, is specified as being particularly well adapted for producing this chemical reaction. A second claim relates to the preparation of cyanides or ferrocyanides by the reaction of a soluble sulphate upon cyanide of barium formed as above, whereby a precipitate of sulphate of baryta is produced. And, thirdly, the partial reconversion of this precipitated sulphate of baryta into carbonate by reduction, in the first place, with charcoal at a high temperature so as to form crude sulphide of barium, and passing carbonic acid gas through an aqueous solution of this product, when a certain quantity of carbonate of baryta will be regenerated and may be used in a repetition of the process.

The chain of chemical reactions called into play in the

porties it appears to resemble Portland cement. A quantity of the finely-ground material is to be stirred up in water and quickly applied as a thin wash to the face of the decaying stone. After a short interval the water will have been absorbed, entering into chemical union with the constituents of the cement, and thus, by filling the cavities and setting hard in the pores of the stone, is said to offer a considerable degree of protection, chiefly by keeping out rain and moisture. According to the circumstances, a second, or even third treatment, at intervals, will be required to secure the best results. This method of protecting stone has been applied by Mr. Griffiths with great success to the walls of houses in the neighbourhood of Whitby, which, from having been constructed of York-shire freestone, an open porous sandstone, allowed the water freely to penetrate in rainy seasons. By a single application of the cement, the stone has been enabled to resist for ten years and upwards the stormy weather which occasionally visits the eastern coast.

In questioning the applicability of a coating of Atkinson's cement to the Houses of Parliament, the Committee have raised doubts, firstly, in regard to its power of sufficiently penetrating the substance of the stone—whether the solid particles of cement would not be separated as by a filter, and form merely a superficial protective crust? and secondly, as to the appearance and texture of the stone after treatment—whether it would not look like stucco? For these reasons it does not appear to be equally well adapted to surfaces of decomposing magnesian limestone and to the coarse-grained, porous sandstones of Yorkshire.

NOTICES OF PATENTS.

437. *The Application of Certain Vegetable Substances to the Manufacture of Paper Pulp.* J. H. JOHNSON, Lincoln's Inn Fields, London. A communication. Dated February 21, 1861.

THE vegetable productions which it is proposed to make use of in the preparation of pulp for paper making are the following—viz., the fir tree, pine, larch, and, in fact, all conifers, junipers, willows, and osiers, tamarinds, broom, and coparia; also the genus juncus, or rush and genista. Amongst herbaceous plants those of the mallow tribe and the bursaria, particularly the bursa pastoris and its varieties; the panicum Germanicum and the tall panicum lupinus, the sorghum, or millet; also those plants of the genus lepidium, or pepper wort, comprised under the order of cruciferae; also the dead leaves of the haricot and pea, and of the thistle. The general treatment to which the above-mentioned vegetable productions are subjected consists, firstly, in boiling them in an alkaline liquor and in draining off this latter as soon as the structures are tolerably softened, then bruising the same in any convenient machine for the purpose of separating the fibres, and afterwards carding, alternately subjecting the loosened fibres to the action of acid and alkaline baths to remove soluble matter and assist disintegration, washing and bleaching by the chloride of lime or any well known process, and finally pressing the pulp into cakes or compact masses easy of transport.

The general mode of treatment here described has during the last few months repeatedly formed the subject of patent claims. It is interesting to remark the identity of language employed in defining the various stages in the unalterable succession of operations which constitute the process for obtaining paper maker's pulp from wood and softer vegetable structures. We have recently had occasion to describe the following patents bearing on this subject:—Indian corn and tanner's refuse (the spent bark of oak or fir) have each been made to furnish ligneous fibre for the purpose of paper making. Specification No. 112,

C. Stevens,¹ details the process of converting wood shavings, and even that of fir, into pulp by boiling with alkali, mechanical tearing, bleaching, &c. And the patent No. 391,² dated but five days earlier than that now before us, refers particularly to the method of treating alternately with acid and alkali as means of expediting the disintegration of the fibre in wood.

454. *Coating and Protecting the Silvered Surface of Looking-glasses or Mirrors.* J. E. COOK, Greenock. Dated February 22, 1861.

FOR the purpose of protecting the mercurial film of looking-glasses from the action of the atmosphere, it is proposed to coat the outer surface of the tin foil with copal or carriage varnish, laid on with a brush in the ordinary manner; the varnish may be used alone, or mixed with any suitable colour. When dry, a solution of shellac is applied as a second coating.

By the employment of alcohol as the solvent in the second varnish, there will be no fear of disturbing the layer of copal previously applied. Such a double coating would probably diminish the tendency to oxidation, but the mirror would, on the other hand, become more liable to mechanical injury from sudden changes of temperature inducing unequal rates of expansion and contraction in the three films, all in absolute contact with each other and with the back of the glass.

456. *Preparation of Red Dyes.* J. MARTIN, Church Row, Limehouse. Dated February 23, 1861. (Not proceeded with.)

THE dyes which form the subject of this invention, are prepared from aniline by the action of nitrate of lead and monohydrated acetic acid. These are mixed together, heated, and subsequently diluted and filtered. For the extraction of the lead compounds from the product, the inventor employs oxalic or other organic acid, with the addition of common salt, which is said to heighten the brilliancy of the colour. Although the nitrate of lead is particularly specified, the inventor claims also the production of red dyes from aniline by the employment of other nitrates yielding oxygen on the application of heat.

A patent has some time previously been granted for the use of the nitrate of mercury as a means of effecting the conversion of aniline into red dye; this circumstance would invalidate the claim stated in the concluding part of the specification, which appears to have been drawn up in too general terms.

455. *Manufacture of Cast Steel.* ROBERT MUSHET, Coleford. Dated February 22, 1861.

473. *Manufacture of Cast Steel.* ROBERT MUSHET, Coleford. Dated February 23, 1861.

THESE inventions have reference to the production of superior qualities of cast steel by the employment of titaniferous iron ore, or other compounds of titanium, in conjunction with the materials ordinarily used in the preparation of cast steel. This admixture may be effected in two ways. Either the titaniferous ore above mentioned, or any native variety of titanic acid, may itself be introduced into the melting pot with the mixture of cast iron, granulated or refined pig iron, and pulverized iron ores, or any other form of oxides of iron and manganese with appropriate reducing agents. Or, secondly, the titanium ore may previously have been reduced by a suitable furnace treatment with deoxidizing agents, to the condition of an alloy of titanium and iron, and in this form added to the melted materials intended to be used in the production of cast steel.

¹ CHEMICAL NEWS, vol. iv., p. 134.

² CHEMICAL NEWS, vol. iv., p. 213.

With a similar object the latter of these patents refers to the employment of the special description of white cast iron termed "spiegel eisen," or of any analogous compound of iron, manganese, and carbon, and such material being alloyed by melting either with the titanium cast steel already described, or with any mixture of substances intended to be used in its production.

These specifications are in continuation of a number of similar patent claims already secured by Mr. Mushet, and which have on former occasions been noticed in our columns. They all refer particularly to the economical employment of the titaniferous iron sand, procurable in great abundance in New Zealand, which is now shown to be so advantageously used in the production of improved qualities of cast iron and steel.

Grants of Provisional Protection for Six Months.

1733. Thomas Cobley, Meerholz, Hesse, Germany, "An improved process for the manufacture of fluo-silicates of lead and baryta, and for the application of the same to various purposes in the arts and manufactures."—Petition recorded July 8, 1861.

1734. Thomas Cobley, Meerholz, Hesse, Germany, "An improved process for the treatment of silicates of metallic and non-metallic bases and other siliceous compounds, as slags, scorings, and such like, in order to recover the said bases, and also in the production of a fluo-silicic and silicic acids."—Petition recorded July 9, 1861.

1775. James Cane Coombe and James Wright, Bridge Street, Blackfriars, London, "Improvements in the manufacture of glass, pottery, porcelain, and other ceramic and plastic wares."—Petition recorded July 15, 1861.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Salts of Fluorine, Silicon, and Mercury.—Pinkener describes (*Poggendorff's Annalen*, Bd. cxi. 248) three compounds of the above bodies. The *silico-mercuric fluoride* is obtained in clear prismatic crystals when a solution of carbonate of the protoxide of mercury in hydrofluosilicic acid is evaporated. Washed with a little water, then pressed between folds of bibulous paper, and afterwards dried over sulphuric acid, these crystals on analysis gave results from which the author calculated the following formula, taking the equivalent of silicon as 21:—

Berzelius' *silico-mercuric fluoride* Pinkener has found to be an hydrated *oxyfluoride*. It is obtained in small acicular crystals on evaporating a solution of mercuric oxide in hydrofluosilicic acid. The composition he found to be

This salt is decomposed by water at the common temperature, forming an acid salt, which remains in solution, and depositing a yellow powder rich in oxide of mercury. The same solution concentrated until the needles begin to form, and then kept at a temperature never exceeding 15° C., deposit clear rhombohedral crystals, united like steps. These deliquesce in the air, and melt in their water of crystallization. Over sulphuric acid they effloresce. They are formed of the *silico-mercuric fluoride*, $\text{Hg Fl}, \text{Si Fl}_2$, and appear to contain six atoms of water.

Double Salts Formed by Iodide of Bismuth.—Lindau has obtained (*Poggendorff's Annalen*, Bd. cxi. s. 240) some double salts with iodide of bismuth, greatly resembling the double salts with iodide of antimony, described by Schaefer (*CHEMICAL NEWS*, vol. ii. p. 143). They are obtained by saturating a concentrated solution of the positive metals with iodide of bismuth, and evaporating the solutions.

Iodide of Bismuth and Sodium forms small red crystals, containing $3\text{Na I}, 2\text{Bi I}_3 + 24\text{HO}$, and apparently is amorphous, with the salt $3\text{Na I}, 2\text{Sb I}_3 + 24\text{HO}$.

Iodide of Bismuth and Ammonium forms beautiful rectangular prisms of a brownish red colour. The powder is vermilion red.

Iodide of Bismuth and Barium is obtained in small rhomboidal crystals of a bright red colour and brilliant lustre. The composition is $2 \text{BaI} \cdot \text{BiI}_3 + 18 \text{HO}$.

Iodide of Bismuth and Calcium has a similar composition to the preceding salt. It forms rhomboidal prisms of a deep red colour and glassy lustre. The powder is carmine red, but nearly black when the water of crystallisation has been driven off.

Iodide of Bismuth and Magnesium ($\text{MgI} \cdot \text{BiI}_3 + 12 \text{HO}$) forms oblique rectangular prisms of a pomegranate red colour. The water of crystallisation cannot be got rid of under a temperature of 175°C .

Iodide of Bismuth and Zinc ($\text{ZnI} \cdot \text{BiI}_3 + 12 \text{HO}$) resembles the preceding, but loses its water at 100°C .

The author could not obtain salts with the iodide of bismuth and iodides of cadmium, iron, and silver. He succeeded in obtaining crystallised compounds with iodide of bismuth and bromides of potassium, sodium, ammonium, magnesia, and zinc, but has not yet examined these salts.

II. ORGANIC CHEMISTRY.

Modifications of Aldehyde.—Lieben (*Sitzungsber. der K. Akad. der Wissenschaften zu Wien*, Bd. li. s. 549) heated iodide of ethyl and aldehyde in a sealed tube to 100°C . The former remained unaltered, but the latter changed to an isomeric modification resembling paraldehyde. It boiled at 123° to 124° , and possessed a vapour density three times that of aldehyde.

Aldehyde, when well cooled, he found to absorb a considerable quantity of cyanogen. The solution, sealed up and left for some time at the ordinary temperature, formed paraldehyde, the cyanogen undergoing no change. When aldehyde is heated in a sealed tube with a strong aqueous solution of either formate of potash, acetate of soda, or the potassio-tartrate of soda, two layers are formed: the lower is the unaltered solution of the salt used; the upper is a slightly viscid yellow liquid, having a penetrating odour. This liquid is very unstable, but, after rectifying with great care, the author determined that it was mainly constituted of a new body, having the composition expressed by the formula $\text{C}_2\text{H}_5\text{O}$. Exposed to the air, it thickens; it reduces oxide of silver, is resinified by potash, and blackens with sulphuric acid. Nitric acid acts on it violently, causing the evolution of much gas, and forming some resinous matter. Heated alone in sealed tube to above 200°C . it changes to a nearly solid black mass and a little water. It is formed, the author thinks, by the elimination of water under the influence of the salt: $2 (\text{C}_2\text{H}_5\text{O} = \text{C}_2\text{H}_4\text{O} + \text{H}_2\text{O})$. Aldehyde heated alone undergoes no change.

Lieben proposes the following rational formula for aldehyde which, he says, lends itself to the interpretation of all the reactions of that body:—

Paraldehyde and elaldehyde he believes (with Geuther and Cartmell) to be identical.

Diamylphosphoric Acid.—Dr. Kraut (*Archiv. der Pharm.* Bd. cxvi. s. 133) obtains this acid by acting on a solution of bromine in fusel oil with phosphorus until the colour disappears. The product is then washed with water to remove the hydrobromic acid, and the oily residue of bromamyl and diamylphosphoric acid is shaken up with a soda solution. The mixture is then boiled to get rid of the bromamyl, and the solution of diamylphosphate of soda is supersaturated with dilute sulphuric acid, whereupon the mixture becomes milky, and oily drops separate. These are taken up by ether; the ethereal solution is washed, evaporated, and dried over sulphuric acid. The acid is not obtained perfectly pure in this way, some substance remaining mixed with it, the exact nature of which is unknown to the author.

Dr. Kraut examined several salts of the acid. **Diamyl-**

phosphate of Lime $2 \text{C}_{10} \text{H}_{11} \text{O} + \text{CaO PO}_3$ was obtained by adding water and milk of lime to the above ethereal solution of the acid. The excess of lime was removed by diluting with a good deal of cold water, passing carbonic acid through the mixture, boiling and filtering. The filtrate was evaporated over a water-bath. The salt forms long snow-white silky needles, which on being dried shrink up to a papery mass; this remains unchanged when heated to 180°C ., and when rubbed becomes electrical. When dropped into water it rotates with great rapidity. It dissolves as easily in cold as in hot water, and is so soluble that the cold saturated solution solidifies when heated.

According to Fehling, the diamylphosphates of the alkalies precipitate the salts of manganese, lead, copper, silver, and mercurous oxide. The cold saturated solution of the lime salt separates only some flocculi from the manganese, copper and silver salts, but gives a large precipitate with the lead and mercury salts. The baryta salt is more soluble in cold than hot water. On heating a cold saturated solution of the magnesia salt, it separates in asbestos-like needles, which settle into a fat-like mass the instant they are removed from the mother liquor.

Diamylphosphoric acid forms an acid and a neutral silver salt. When shaken up with moist silver oxide, separated from the excess, and evaporated, microscopic needles of the acid salt are obtained. These dried over oil of vitriol remain unchanged at 120° , and have the composition $2 \text{C}_{10} \text{H}_{11} \text{O} \cdot \text{AgO PO}_3 + 2 \text{C}_{10} \text{H}_{11} \text{O} \cdot \text{HO PO}_3$. The neutral salt is obtained by decomposing a solution of sulphate of silver in hot water with an equivalent weight of the baryta salt. It has the formula $2 \text{C}_{10} \text{H}_{11} \text{O} \cdot \text{AgO PO}_3$.

When submitted to dry distillation, the salts of diamylphosphoric acid yield a clear liquid, and leave a residue of a metaphosphoric acid salt scarcely blackened by carbon.

MISCELLANEOUS.

Adulteration of Food.—The Cheltenham Board of Guardians have appointed Mr. Horsley, the County Analyst, at a salary of ten guineas per annum, to analyse the provisions supplied for consumption in the Union Workhouse.

ANSWERS TO CORRESPONDENTS.

* * All Editorial Communications are to be addressed to the EDITOR; and Advertisements and Business Communications to the PUBLISHER at the Office, 1, Wine Office Court, Fleet Street, London, E.C.

T. Falconer.—The solvents vary according to the mode of preparation. In some cases alcohol, in others dilute acetic acid, and in some few water will be found the best solvent.

D. Knight.—The best practical information with which we are acquainted on the subject of grinding lenses is in a pamphlet published by Secretan, of Paris, entitled, "De la Distance Focale des Systemes Optiques convergents." It costs about 2s. 6d. to 3s.

Red Ink to be used with Steel Pens.—J. M.—We do not know a good receipt. Those which we have tried have not answered our expectations. The suggestion shall be attended to if possible.

W. B.—The crust formed on the leaden top of your inkstand is probably carbonate of lead, formed by the acid and aqueous vapours from the ink. As a remedy use India-rubber varnish, or deposit silver on it electro-chemically.

J. Horsley.—It is withdrawn as you request. Our examination of the sample sent coincides with yours. We shall be glad to receive the full statement promised.

W. Stevenson.—Received.

A. H. B.—1. Allow it to digest in a mixture of alum, salt, and nitre, dissolved in water. 2. See our previous volumes. 3. The zinc plates need not be quite so large as the silver, but more than half the size.

A Subscriber.—Boil them with dilute hydrochloric acid and copper. Test the copper subsequently in the usual way. We do not think arsenic is present; it is scarcely ever used now for that purpose.

THE PRESERVATION OF STONE.

IN another column will be found an abstract of the plan, which was submitted on 17th May last, by the Editor of this Journal, to the Committee on the Decay of the Stone at the New Palace at Westminster, with the view of hardening and preserving it from further decay. Since that period we have unremittingly pursued our experiments on the subject, both with the plan above referred to, and various others, which were suggested by reactions incidentally noticed in the course of the investigation, and it is to one of these offshoots of our experiments that we wish now to draw attention.

No one who has critically examined the various projects for hardening and protecting stone, which have during the last few years been made public, can have failed to remark the great importance, which, in the majority of instances, is attached to the action of silica. Thus, in reviewing the processes submitted to the Decay of Stone Committee, among the eleven proposals which have already been under consideration, no less than seven depend for their efficacy upon the action of this very substance under various conditions of employment. Advantage is taken of the mutual decomposition exerted between certain silicious compounds applied, and the materials constituting the building stone itself; or, otherwise, systems are founded upon the production of compounds from an alkaline silicate, and a soluble earthy salt successively applied. The known properties of silica and of the class of silicates have, no doubt, powerfully contributed to the formation and establishment of this opinion. The facility and cheapness with which they can be manufactured on the large scale; their inalterability under trying atmospheric influences; their all but complete indifference to energetic chemical reagents—all point to silica as the one fit material upon which the ingenuity and experimental resources of our chemists and practical men may be expended with the greatest promise of success. Let only a sufficient amount of silica be compelled to enter and occupy the pores of the stone and incrust all the exposed surfaces; let it be employed in a state of hydration or other suitable form in which it may gradually combine with the earthy constituents it there meets, and with its action unfettered by saline impurities the presence of which tend often to interfere mechanically with its successful employment, and the strong presumption is that the Houses of Parliament will endure, so far as the stone is concerned, as long as the Pyramids.

The difficulty which besets many of the processes of silicification is, that along with the needful silica, so much superfluous, and, indeed, injurious matter is introduced that the valuable qualities of the silica are in a great measure counteracted; the disintegration of the stone sometimes caused actually by the efflorescence of these extraneous substances, and the porous character necessarily induced as the consequence of the gradual removal of the soluble salts in juxtaposition with the silica, almost undoing the binding and hardening action

of this valuable material. From this train of reasoning, it became evident that if hydrated silica could but be deposited in the pores of a limestone or dolomite, without the assistance of potash or soda as a vehicle, and there be left slowly to enter into chemical union with the earthy bases of the stone, its action commencing unimpaired by the presence of extraneous salts, and its future efficacy undiminished by the progress of their removal,—that if this could be accomplished, there would be a far greater chance of ultimate success than has been offered by any plan yet made public.

It is well known that silica can, by appropriate means, be obtained in the form of a pure aqueous solution, and it was to this liquid that we accordingly directed our attention. This solution can be made in several ways:—

1. By dissolving sulphide of silicium in water, when sulphuretted hydrogen is given off, and the silica remains completely dissolved, and in such quantity that the liquid gelatinises when an attempt is made to evaporate it.

2. By precipitating silica in the gelatinous state from an alkaline silicate, by means of acetic or other weak acid, and, after well washing, heating it for some time under pressure, with a small quantity of water in a closed vessel. A liquid is thus obtained which gelatinises on addition of a saline solution.

3. By passing gaseous fluoride of silicium over crystallised boracic acid, and separating the hydrofluoric and boracic acids by digestion with a large excess of ammonia, a hydrate of silica remains, which, when well washed from the above acids, is very soluble in water. This solution gives no precipitate when boiled, but leaves silica as an insoluble powder on evaporation.

4. By the beautiful method recently pointed out by Professor Graham, in which advantage is taken of the new means of separating bodies by *dialysis*. A solution of silicate of soda, supersaturated with hydrochloric acid, is placed on one side of a parchment paper septum, pure water being on the other side; in a few days the hydrochloric acid and chloride of sodium will be found to have completely passed through the diaphragm, leaving the silica in aqueous solution, and so pure that acid nitrate of silver fails to detect chlorine in the liquid. This solution remains fluid for some days, but it ultimately gelatinises. We have generally adopted this last plan of preparing the aqueous solution of silica, although a stronger solution is obtained by the method first given.

When a pure aqueous solution of silicic acid prepared as above is allowed to soak into the pores of chalk or dolomite, a process of hardening rapidly occurs, which goes on increasing for several days, whilst, owing to its considerable depth of penetration, and to there being no soluble or efflorescent compounds to be removed, there is every probability that this hard silicious impregnation will afford permanent protection to the stone. We are now actively engaged in investigating the nature of the action which takes place, and already several curious and important results have been made out, from which we are led to anticipate that our experiments will ultimately be rewarded with complete success.

SCIENTIFIC AND ANALYTICAL
CHEMISTRY.

Researches on the Relations existing between Atomic Weights, by M. J. S. STAS, Member of the Royal Academy of Belgium.

(Continued from page 218.)

Synthesis of Chloride of Silver.—I have determined the proportional relation between silver and chlorine,—
1st. By the direct combustion of the metal in chlorine, as has already been performed by M. Dumas.

2ndly. By dissolving silver in nitric acid, precipitating the nitrate by means of gaseous hydrochloric acid conducted to near the surface of the solution; evaporating the whole to dryness in the same vessel, and fusing the resulting chloride in an atmosphere of hydrochloric acid gas, afterwards replaced by air.

3rdly. By dissolving silver in nitric acid, precipitating by aqueous hydrochloric acid, washing the precipitate in water acidulated with nitric acid, fusing the chloride in an atmosphere of hydrochloric acid, and evaporating all the liquids out of contact of air, to collect the chloride carried down or dissolved by them.

4thly. By dissolving silver in nitric acid, precipitating the nitrate by a solution of pure sal-ammoniac, washing the chloride in acidulated water, and fusing it in an atmosphere of hydrochloric acid; then evaporating out of contact of air all the washing waters (after having passed through them a current of chlorine to destroy the nitrate of ammonia formed and the excess of sal-ammoniac employed), to collect the chloride carried down or dissolved.

These methods, which, however, have already been employed, have all given the composition generally admitted for chloride of silver; they present causes of error which I shall point out when detailing the results given by each.

I. Synthesis of Chloride of Silver by the Action of Chlorine on Silver heated to Redness.—To effect the combustion of silver in chlorine, I have taken a tube of Bohemian glass, bent in such a manner that the silver in lumps or sheet was contained in a portion very slightly inclined, so that the chloride as it was formed should be carried by the chlorine into a horizontal portion, which served as a receiver. This horizontal portion was bent upwards again very slightly to avoid loss of chloride. The tube and the silver were weighed separately. All that part of the tube which was to be heated was surrounded with a thin sheet-iron case, filled with pure magnesia. This case was not heated to redness until the pure dry chlorine which traversed the tube had been passing sufficiently long to completely drive out all the oxygen.

The complete chloruration of 100 grammes requires a slow and uninterrupted current of chlorine for at least fifteen hours. It is likewise necessary to take the greatest precaution to prevent any trace of silver escaping the action of the chlorine. Thus, out of five experiments that I made, two were vitiated owing to particles of silver being surrounded with fused chloride, and thus remaining unattacked.

The synthesis of chloride of silver by this method is liable to three sources of error or uncertainty. The first is the mechanical carrying away of the chloride of silver by the current of chlorine. Having found this out in the first experiment, I tried to obviate the inconvenience by allowing no more chlorine to pass over the silver than

it would absorb. I cannot describe without a drawing the arrangement of apparatus which I devised for this purpose; I give it in my memoir.

The second inconvenience is the absorbent power which the fused chloride has for chlorine. To obviate this source of error, I caused to pass in one experiment a current of air, and in two others a current of dry carbonic acid over the fused chloride, but after having previously noted the weight of the chloride.

Finally, the third source of error is the attack of the glass tube by chloride of silver, which is kept long fused in contact with it. There is thus produced an alkaline chloride, which volatilises in the current of chlorine. I am not quite certain whether this attack takes place with disengagement of oxygen or chlorine, but the augmentation of the weight of the tube is a constant fact.

To sum up, this method, which at first sight appeared so simple, leaves grave doubts as to its results, if these are not confirmed by those obtained by means of other methods.

Below is given the result of three experiments which I succeeded in bringing to a satisfactory conclusion:—

Synthesis of Chloride of Silver by the Combustion of Silver in Dry Chlorine.

Numerical Order.	Weight of the Silver in air.	Weight of the Silver reduced to a vacuum.	Weight in air of the Chloride of Silver fused in chlorine.	Weight in vacuum of the Chloride of Silver fused in chlorine.	Weight in air of the Chloride of Silver fused in a slow current of carbonic acid.	Weight in vacuum of the Chloride of Silver, after eliminating the dissolved chlorine.	100,000 parts of Silver produce	
							A.—Chloride saturated with chlorine.	B.—Chloride freed from dissolved chlorine.

II. Synthesis of Chloride of Silver, by dissolving Silver in Nitric Acid, precipitating the Nitrate by means of Gaseous Hydrochloric Acid conducted to near the Surface of the Solution, evaporating the whole to Dryness in the same vessel, and fusing the resulting Chloride in an Atmosphere of Hydrochloric Acid Gas, afterwards replaced by a Current of Air.—Almost all my syntheses of chloride, and nitrate of silver and lead, have been made in the same apparatus. A drawing of this is given in my memoir. I will here describe it in a few words. The apparatus consists of a globe or matrass of Bohemian glass of a convenient size, according to the quantity of the metal to be dissolved, to the neck of which is adapted a flask of the same glass, the bottom of which is removed. To the narrow opening of this flask I adjust hermetically a system of bulb tubes, which serve to wash the gas traversing them, so as to retain the nitrate carried away by the nitrous vapours during the solution of the metal. The bulb-tube has a vertical branch leading into a small globe of water. The last trace of metal is thus arrested.

In order to attach the globe conveniently to the balance, I have arranged a system of platinum wires by which to hang it; these during the experiment do not come in contact with acids.

The globe, with the flask attached to it, being weighed, and the weight verified the next day,—a precaution which I have taken in all my syntheses,—I introduce into it the silver in small bars, and then pour in the nitric acid which has immediately before been distilled. Holding the neck of the globe almost horizontal, I adapt it to the flask with the tube, containing in its bulbs a convenient quantity of pure water, and fix the whole in this position. The globe is then carefully heated in an air bath. During the solution of the metal, I take care that the temperature never rises above 50° or 60°, otherwise the action is too energetic, and in spite of all precautions silver is carried through the condensing apparatus. Three or four hundred grammes of silver require at least thirty-six or forty-eight hours' action to dissolve in nitric acid of a strength of 40°, or even 25°, Baumé.

When the solution is complete, I remove the bulb-tube and the flask from the globe, taking care always to keep this in its original position—that is to say, with the neck almost horizontal. I then pass into it a slow current of hydrochloric acid, continuing the current until the liquid, set in motion by the rotation of the globe, becomes turbid. I then insert the neck of the globe as far as possible into the mouth of the receiver, and gently incline the whole of the apparatus, so that the vapour which condenses in the neck cannot run back. I heat the liquid in the globe by means of an air-bath to a temperature which approaches, but which must never reach, its point of ebullition. When almost all the liquid is volatilised, I again pass hydrochloric acid gas into the globe without allowing it to cool, and always keeping it in the inclined position. Dark red vapours are immediately formed, which soon give place to pure gaseous hydrochloric acid. I then evaporate it completely to dryness, and heat the chloride to its fusing point.

I have sometimes weighed the chloride dried at its fusing point, in order to ascertain the quantity of nitrate of silver which it retains when it is precipitated from a concentrated solution of this salt. This quantity is very variable, but its presence is a constant occurrence. In order to obviate the augmentation of weight which it causes, I filled the globe with hydrochloric acid, and kept the chloride in a state of fusion as long as orange-yellow vapours appeared; but taking the precaution not to raise the temperature beyond the fusing point, for fear of attacking the glass and decomposing the chloride itself. I then replaced, with the aid of heat, the atmosphere of hydrochloric acid by one of dry air.

From the moment of its formation until after weighing the chloride of silver was completely kept from the action of light; thus, in these experiments the chloride of silver remained of a pearly white. The globe has been but rarely attacked; at the most there were to be noticed here and there some yellowish-brown spots on the glass. When the operation is terminated, the globe is fitted with the flask, which serves as a stopper for it. In order to prevent moisture from penetrating during its cooling, I adapt a chloride of calcium tube to the flask. When it is quite cool I wash the globe with water, and, after having wiped it dry, I suspend it to the beam of the balance and allow it to remain at rest for several hours.

The acid liquid which volatilises has always been evaporated a second time in a porcelain dish to see if silver be present in the residue, which I have always found. When reduced to a twentieth of its volume, I have added to it the contents as well as the rinsings of the bulb-tube and the flask through which the gas

evolved during the solution of the silver was passed; the chloride obtained in this manner was weighed separately.

Two causes of error can affect the result, but they act in an opposite manner. One of them tends to increase the weight from impurity in the acids, or from the vessels being attacked. I have sufficiently explained in the introduction how I have removed this cause of error; I think I may safely say it does not exist. It is probable, on the contrary, that there is a slight loss of weight owing to the chloride of silver being carried away by the chloro-nitrous vapours which are produced during the fusion of this body in an atmosphere of hydrochloric acid to remove the nitrate of silver, whether this nitrate exists already in the precipitate formed in a concentrated solution of silver in nitric acid, or whether it has been formed by the direct action of the nitric acid on the chloride during the evaporation of the liquid acid.

Below I give the results of two experiments made by this method:—

Syntheses of Chloride of Silver.

Numerical Order.	Weight of the Silver in air.	Weight of the Silver reduced to a vacuum.	Weight of the Chloride of silver obtained from the silver carried off during the solution of the metal and the evaporation of the liquids. III. Synthesis of Chloride of Silver by dissolving Silver in Nitric Acid, precipitating the Solution with a slight Excess of Hydrochloric Acid, washing the Precipitate, fusing the Chloride in Hydrochloric Acid Gas, and evaporating all the Liquids out of contact of air to recover the Chloride carried down or dissolved.—The solution of the silver was effected in an apparatus identical with the one previously described. The contents of the bulb-tube and the flask employed to condense the nitrate carried off by the gas, as well as the washing-waters of these two apparatus, were added to the contents of the globe. After complete cooling of the liquid, I carried the globe into a dark room, introduced a slight excess of hydrochloric acid, and shook the resulting chloride for at least twenty minutes to divide it, and to transform as completely as possible all the nitrate into chloride. At the end of that time the contents of the globe were heated to 100°. By the action of heat, the liquid became perfectly clear and the chloride had greatly contracted. The next day I decanted the liquid, with the greatest precautions. The globe, still remaining inclined, was then heated in a bath to 100°; there thus run from the chloride a fresh quantity of very clear liquid. I then poured into the globe, boiling water, very slightly acidulated with nitric acid; the chloride was then agitated to divide it afresh. The next day the liquid, which had become clear, was again decanted. The globe being placed in a very inclined position, was heated, and all the liquid produced by the contraction of the chloride under the influence of heat was decanted and added to the preceding waters. The chloride was thoroughly dried, then fused in an atmosphere of hydrochloric acid, which, as soon as fusion commenced, instantly eliminated chloro-nitrous vapours. The atmosphere of hydro-

chloric acid was then replaced by pure dry air. The chloride obtained was pearly white.

All the decanted solutions and the liquids obtained by drying the chloride were evaporated. In the experiment which I made in this manner on 99.9925 grammes of silver, the total volume of these liquids amounted to 2510 cubic centimetres. When evaporated they left a residue the total weight of which was 0.0063 grammes, containing 0.0035 grammes of chloride of silver, the rest being composed of traces of chloride of copper and of alkaline and earthy chlorides.

This experiment gave the following results:—

Synthesis of Chloride of Silver.

Numerical Order.	Weight of the Silver in air.	Weight of the Silver reduced to a vacuum.	Weight of the Chloride of Silver obtained from the evaporation of the washing waters.	Weight in the Chloride of Silver fused in hydrochloric acid gas.	Total weight of the Chloride of Silver reduced to a vacuum.	100,000 parts of Silver produce of Chloride of Silver
VI.	grmms. 99.9965	grmms. 99.9925	grammes. 0.0035	grammes. 132.825	grammes. 132.8382	132.848

IV. Synthesis of Chloride of Silver by dissolving the Metal in Nitric Acid, precipitating the Solution with Chloride of Ammonium, washing the Precipitate, and fusing the Chloride in Hydrochloric Acid Gas.—This determination was made under absolutely the same conditions as the preceding, with this exception, that the hydrochloric acid was replaced by sal-ammoniac, and that the washing-waters and that derived from the drying of the chloride, before being evaporated, were submitted to a current of chlorine to destroy the excess of sal-ammoniac and of the nitrate of ammonia which was formed. The evaporation of these left me an appreciable quantity of chloride.

A synthesis made in this way with silver prepared from the acetate gave me the following result:—

Numerical Order.	Weight of the Silver in air.	Weight of the Silver reduced to a vacuum.	Weight of the Chloride of Silver derived from the metal carried down and dissolved by the washing waters.	Total weight of the Chloride in air.	Weight of the Chloride reduced to a vacuum.	Chloride of Silver produced by 100,000 parts of this metal
VII.	grmms. 98.3175	grmms. 98.3140	grammes. 0.0360	grammes. 130.5925	grammes. 130.602	132.8417

Thus, my syntheses of chloride of silver have given the following results:—

1. By the combustion of silver in chlorine	100,000 parts of silver.	I. 132.841
2. By the precipitation of silver with hydrochloric acid without washing the chloride		II. 132.843
3. By the precipitation of silver with hydrochloric acid with washing the chloride		III. 132.843
4. By the precipitation of silver with sal ammoniac and washing the chloride		IV. 132.849
		V. 132.846
		VI. 132.848
		VII. 132.8417
		Mean.. 132.8445

Since the sixth determination, in which an increase of weight is impossible, has given from 100,000 parts silver 132.848 parts of chloride, I consider the mean of 132.8445 as being above the truth; and I think we ought to admit that, within the limits of experiment, 100,000

parts of silver produce 132.850 parts of chloride. Hence it results that the proportion which silver bears to chlorine is in the ratio of 100,000 : 32.850.

(To be continued.)

On the Adulteration of Butter, by JOHN HORSLEY, Analyst to the County of Gloucester.

A short time since the question was put by one of your correspondents as to whether there was any method of detecting lard in butter, which I have much pleasure in answering.

In order to distinguish between pure butter and that adulterated with lard and other substances, proceed thus:—

First satisfy yourself, by melting a portion of the suspected butter over a water-bath, and observing if there be any insoluble admixture of farinaceous matter, such as wheat-flour, potato-starch, arrow-root, or turmeric (said to be sometimes used), which the microscope and chemical tests will prove; then mix the melted butter in an evaporating-dish with four or five times its bulk of hot water, and allow it to stand for two or three hours to collect on the surface and solidify. Detach the resulting cake of butter, and place it on a piece of blotting-paper to dry, by the absorption of all adhering aqueous matter. If a piece of this prepared butter be introduced into a wide-mouth stoppered bottle, and surrounded with ether, at the temperature of 65° Fahr., it ought to entirely dissolve, forming a clear lemon-yellow coloured liquid.

On the other hand, the purest lard, which, on being melted, leaves no residue, is more or less insoluble in ether at that temperature, as a thick milky fluid results, which, on standing, deposits to a considerable extent. The same may be said of other fats, such as dripping, mutton suet, tallow, &c., the precipitates from which are of a much coarser and flocculent character than that from lard in ether. Hence we perceive there is a striking peculiarity about butter, which, if treated as above, enables us to readily determine its purity and the probable proportion of foreign fatty matters mixed with it. The solution of lard and other fats in ether is considerably influenced by temperature, for if the bottle containing them be held in the hand a short time liquefaction takes place, but on a reduction of temperature they are again precipitated. The character also of the various precipitates is remarkable, and gives us some clue to their nature,—the precipitate from lard being very fine and smooth, whilst that of dripping is granular and crystalline, and that from tallow long and thread-like, laying piled up one above the other. A solution of butter in ether, exposed to a less temperature than stated, yields beautiful stellar-like tufts of very fine acicular crystals.

The Laboratory, Police Station, Cheltenham.

On the Effects of Reducing Agents upon Nitrates of Ethyl, by M. CAREY LEA.

As ammonia under the influence of oxydizing agents is burned to nitrous and nitric acids, so these acids when acted upon by reducing agents, might naturally produce ammonia, or in the presence of a decomposing ethyl compound, might give rise to the formation of substituted ammonias. The experiment, however, seems to prove that while ammonia is a constant result of this reduction, it varies greatly in quantity according to the particular

reducing agent employed, and that substituted ammonias are not produced, at least not in recognisable quantities. The following were the reactions observed:—

Reduction by Protochloride of Tin.—Alcoholic solution of protochloride of tin added to nitrate of ethyl causes violent effervescence, but no disengagement of nitrous fumes. The solution of protochloride was added until reaction ceased. The whole was then distilled with caustic potash and the resulting gases conducted into dilute chlorhydric acid, which by evaporation left only a film of substance—this gave, on examination, distinct indications of ammonia.

Reduction by Sulphydic Acid.—A large quantity of sulphydic acid was conducted through nitrite of ethyl. Slight effervescence was produced and much sulphur deposited. The liquid filtered from the sulphur proved to contain a large quantity of ammonia, but no ethylamine, di-, or tri-ethylamine, although the mode of examination employed would have detected a very small quantity if present. After the removal of the ammonia, the solution heated with PtCl_4 gave a small quantity of a brown precipitate of a platinum salt, which when heated glowed for a long time, showing the presence of much carbon, and finally left a residue of reduced platinum. The amount obtained was too small for investigation, but 20 or 25 milligrammes of Pt salt were obtained from the decomposition products of 50 grammes of nitrite of ethyl.

This result, therefore, as far as the production of ammonia corresponds with that obtained by M. Emile Kopp,¹ although, as that chemist employed sulphydrate of ammonia instead of sulphydic acid, it does not appear that the production of ammonia by the reaction itself, could be positively established.

Reduction by Ferrous Acetate.—Nitrite of ethyl was added to about three times its bulk of ordinary acetic acid, and sufficient alcohol to make them mix. To this mixture iron filings were added. A powerful action set in without aid of heat. Deutoxyde of nitrogen was evolved in considerable quantity. When action had ceased, the resulting liquid was filtered, evaporated with chlorhydric acid and distilled with caustic potash. The distillate contained only traces of ammonia.

The effect of the reducing agents on nitrite of ethyl is therefore very different. Only with sulphydic acid was any considerable quantity of ammonia produced, and only with ferrous acetate was deutoxyde of nitrogen evolved.—*American Journal of Science*, No. 95.

Chemical Researches on the Assay of Silver by the Moist Way, by G. J. MULDER, *Math. Mag. Phil. Nat. Medicinæ, Artis Obstetriciæ et Pharmaceuticæ Doctor, Professor of Chemistry at the University of Utrecht, Grand Cross of the Order of the Netherlands Lion; of the Luxembourg Order of the Couronne de Chêne; of the Swedish Orders of Wasa and Polar Star, &c., &c.*

(Continued from page 206.)

In order to enable us to survey the whole phenomenon, we must start from this point of neutrality, leaving aside for the present the question whether this is precisely the point of true chemical neutrality.

In the liquid brought to the point of neutrality, solution of silver and salt produce a precipitate which is of the same strength in each case, the precipitate produced by silver taking, however, a longer time ere it makes its

appearance.¹ The liquid, therefore, which is precipitable in this way, by means of solution of salt and silver, undeniably contains nitrate of silver and chloride of sodium at the same time; for if the clear liquid which we say has reached the point of neutrality—i. e., in the first given instance after addition of ten, and in the latter instance after addition of thirty drops of the decimal solution of silver—did not contain silver in solution, chloride of sodium would not yield a precipitate of chloride of silver; and if, on the other hand, chloride of sodium were not present, nitrate of silver, on being added, could not give rise to a precipitate.

The clear liquid, therefore, brought to the so-called neutral point, contains nitrate of silver and chloride of sodium together in solution, combined in a peculiar manner, but not so intimately that the proper chemical affinity is quite suspended; for we find that if the clear liquid be divided into two equal portions, the addition of chloride of sodium to the one-half produces a precipitate of chloride of silver, while addition of solution of nitrate of silver produces a precipitate of chloride of silver, subtracting the chlorine from the chloride of sodium. The following table will illustrate this point:—

	I. The one half of the liquid brought to the point of neutrality.	II. The other half of the liquid brought to the point of neutrality.
Contains . . .	NO_2AgO ClNa	NO_2AgO ClNa
Added to it . .	NO_2NaO ClNa	NO_2NaO NO_2AgO
Produces insoluble	ClAg	ClAg
Retains in solution	ClNa NO_2NaO	NO_2AgO NO_2NaO

Although we have not entered into anything very strange, it will be as well to discuss more explicitly the simultaneous existence of NO_2AgO and ClNa . Let us return again to the experiment with three grammes of silver. Let us suppose that we have obtained the whole of the solution clear, after addition of thirty drops of solution of silver and subsequent shaking and settling of the precipitate, and, further, that we have divided the solution into two equal parts. Now, it is asked, what quantity of decimal solution of salt and decimal solution of silver can each portion of liquid bear in order to reach the limit of precipitability. It is difficult to solve this question by experiment, but from all that has been mentioned already, the answer to this question cannot be deemed a difficult one; for in order to reach the ultimate limit of precipitate, in the one half of the liquid of the solution of one gramme of silver, there will be wanted five drops of the decimal solution of salt, while in the other half of the same solution five drops of decimal solution of silver will be wanted. In the case, however, where three grammes of silver have been dissolved, the one half of that solution will require

¹ It is worthy of notice that the colour of the precipitate produced by the addition of nitrate of silver to solution of salt is slightly grayish; while, on the other hand, the precipitate produced by chloride of sodium in solution of silver has a perfectly white colour, the same may be observed when the experiments alluded to are made,—viz., the mutual precipitation. The precipitate in both cases is of different physical quality—only when formed in so greatly-diluted solutions as are here spoken of—from the ordinary precipitate of chloride of silver. This difference in the appearance of the precipitate is not merely due to the greater state of division owing to its formation in a very much diluted solution; but invariably the precipitate will be found characteristic and different from what it normally is as soon as one has reached that limit where a precipitate ceases to be formed, even when that limit is cautiously sought for while using the standard solutions one cannot fail to find this to be the case.—M.

fifteen drops of the decimal solution of salt, the other half fifteen drops of the decimal solution of silver.

In order to reach the limits of mutual precipitation, one gramme of silver dissolved required 20 drops; half of this is neutralised by 10 drops. If the last 20 drops added were solution of salt, then the 10 required will be silver. If the whole mass of liquid be divided into two equal parts, in the one-half 5 drops of salt, and in the other half 5 drops of silver solution will find material for precipitation. When we had to do with the solution of 3 grammes of silver, we first required 60 drops, which were neutralised by 30 drops of the reagent, and the mass of liquid being divided into two equal parts, 15 drops of decimal solution of salt, added to the half portion, and 15 drops of decimal solution of silver to the other half, will find material for precipitation in each of the glasses which contain the liquids just alluded to.

It may, perhaps, not be out of place to elucidate these matters by bringing them in the shape of a table, as follows:—

	1 gramme of Silver	3 grammes of Silver
	Require [after having been precipitated by solution of salt to the ultimate limit, temper- ature being from 15° to 17° C.] cubic centimetres of decimal solutions.	
	c. c.	c. c.
In order to be carried to the ultimate limit of the precipitate of silver, solution of nitrate of silver	1	3
In order to reach the point of neutrality, requires addition of solution of common salt	0.5	1.5
If the mass of liquid is now equally divided into two test glasses, each glass will exactly take of solution of nitrate of silver and of solution of common salt	0.25	0.75

I now return to what I have called mutual precipitation. In case the explanation given of what exists in the liquid when the point of neutrality² has been reached is correct, then it will not be difficult to explain how it is possible that—when one commences, for instance, from the ultimate point reached in making a silver assay, viz., after addition of solution of salt precisely in the quantity necessary for precipitation,—decimal solutions of silver and salt may be added, *vice versa*, until the limit of precipitability shall have been reached, and then back again, even an unlimited number of times, provided the chloride of silver does not change its colour.

In order to give this explanation in full, I will start from that moment when, in making the experiment, one has reached, on addition of decimal solution of salt, the limit of a visible precipitate. The liquid under experiment then contains what is mentioned in Table 1, viz., ClNa , NO_3NaO . And this being so, decimal solution of silver will yield a precipitate of chloride of silver. Let us take up the experiment again where we have 3 grammes of silver solution temperature 15° to 17° C., and let us add decimal solution of nitrate of silver, drop by drop, until 30 drops shall have been added, then there exists in that liquid what will be indicated below at A, while if we go on adding decimal solution of nitrate of silver, so that we pass over the neutral point (and this will happen with from 31 to

60 drops), there will take place in the liquid what will be found below in Table B.

A.—From 1 to 30 drops of nitrate of silver,—

The liquid contains . . .	Cl Na $\text{NO}_3 \text{NaO}$
Added	$\text{NO}_3 \text{AgO}$
Produces insoluble . . .	Cl Ag $\text{NO}_3 \text{AgO}$
There remains in solution	Cl Na $\text{NO}_3 \text{NaO}$

Neutral Point.

B.—From 31 to 60 drops of nitrate of silver,—

The liquid contains . . .	$\text{NO}_3 \text{AgO}$ Cl Na $\text{NO}_3 \text{NaO}$
Added	$\text{NO}_3 \text{AgO}$
Produces insoluble . . .	Cl Ag $\text{NO}_3 \text{AgO}$
There remains in solution	$\text{NO}_3 \text{NaO}$

Between A and B is the place of the neutral point, at which nitrate of silver, as well as chloride of sodium, yield an equally strong precipitate.

I will now give a sketch of what will exist after B shall have been treated with 60 drops of decimal solution of salt (solution of 3 grammes of pure silver, temperature 15° to 17° C.), when one requires the ultimate limit of precipitability:—

C.—From 1 to 30 drops of solution of salt,—

The liquid contains . . .	$\text{NO}_3 \text{AgO}$ Cl Na $\text{NO}_3 \text{NaO}$
Added	Cl Na
Produces insoluble . . .	Cl Ag $\text{NO}_3 \text{AgO}$
There remains in solution	Cl Na $\text{NO}_3 \text{NaO}$

Neutral Point.

D.—From 31 to 60 drops of solution of salt,—

The liquid contains . . .	$\text{NO}_3 \text{AgO}$ Cl Na $\text{NO}_3 \text{NaO}$
Added	Cl Na
Produces insoluble . . .	Cl Ag Cl Na
There remains in solution	$\text{NO}_3 \text{NaO}$

I hope I have herewith proved the *de facto* existence of mutual precipitation, and that this matter will be pretty clear now.

The following scheme may suffice for elucidation:—When the ultimate limit has been reached, the liquid, provided nothing more be added, contains dissolved:—

For Salt.	For Silver.
Cl Na	$\text{NO}_3 \text{AgO}$
$\text{NO}_3 \text{NaO}$	$\text{NO}_3 \text{NaO}$

Whence it is evident that in the first case, where silver meets common salt, it will yield a precipitate; while, on the other hand, chloride of sodium meeting with silver will produce a precipitate. From the facts just alluded to, it is quite evident, that he who makes an assay by adding solution of salt as long as a perceptible precipitate is produced, adds more salt than will be required for the silver according to equivalent proportions.

In case this were not true, the whole explanation given would be incorrect; and that explanation is no hypothesis, but the simple expression of facts.

(To be continued.)

² Point of neutrality means that where decimal solution of silver and decimal solution of salt yield an equally strong precipitate.

TECHNICAL CHEMISTRY.

Description of a Gas Furnace for General Chemical Use, by JOHN JOSEPH GRIFFIN, F.C.S.

I HAVE already published descriptions of several gas furnaces, adapted to special purposes.¹ The present notice refers to a simple form of gas-burner, which, aided by suitable fittings, can be used as a convenient source of heat for most operations of the chemical laboratory and lecture table. It will boil a quantity of liquid, exceeding two gallons at once; it will raise a 4½ inch fire-clay crucible to full redness; it will fuse anhydrous carbonate of soda in greater quantity than is required for the analysis of a siliceous mineral; and it will melt small quantities of sterling silver. This amount of power is sufficient for most chemical operations that are not metallurgic.

The Gas Burner.—Fig. 1 represents the gas-burner

Fig. 1.

of this apparatus. The gas is supplied by the horizontal tube, whence it passes through a set of small holes into the box *c*, in which it mixes with atmospheric air that enters freely by the holes shown in the sketch. The gaseous mixture passes up the vertical tube *b*, and is inflamed at the top, where it burns with a single, tall, blue flame, which gives no smoke, very little light, but much heat. In this condition, the apparatus differs from "Bunsen's Gas-burner" only in size. *c*, represents a thin brass cap, which fits the air-box *a*, but moves easily round it. *d* is a flat, cast-iron box, with many holes round the margin, and a few small ones on the top. This box fits loosely on the upper part of the tube *b*, and when it is placed upon it, and the gas is lighted, the flame produced consists of a series of radiating jets, forming a horizontal circular flame of about 7 inches in diameter.

Fig. 2.

Fig. 2.—*a* shows a ring of horizontal flames thus produced, and *b* shows the single vertical flame.² The ring of flame is suited to the purposes of boiling and evaporation; the single flame to ignition and fusion. The height of the apparatus represented by Fig. 1 is 12 inches; the bore of the tube *b* is 1 inch; and the diameter of the fire-box *d* is 4 inches.

Bunsen's gas-burner, whatever its size, is subject to two defects: sometimes the flame burns white and smoky, and sometimes it blows down, the gaseous mixture explodes, and the gas then burns with a smoky flame in the air-box *a*, Fig. 1. The remedies for these defects are as follows:—If the flame is white only when the gas is turned on very full, the remedy is to lessen the supply of gas; but if the flame continues to burn white at the top when the gas is gradually turned off,

and the mass of flame slowly sinks, then the holes which deliver the gas from the supply pipe into the air-box are too large, and are placed too directly under the centre of the vertical tube *b*, Fig. 1, and these defects must be corrected in the instrument. Finally, when the flame blows down, it is because the supply of atmospheric air is too large in proportion to the supply of gas, and their relative proportions must be altered. To effect this alteration, the cap *c* is to be turned round on the air-box *a*, so as partially to close the holes, and thus lessen the supply of air. If, when the gas is alight, the flame needs to be lowered, first the supply of air is to be lessened, and then the supply of gas. If the flame is to be enlarged, first the supply of gas must be increased, and then the supply of air. In short, to prevent the flame blowing down, the gas must always be first placed in excess, and then have the proper quantity of air adjusted to suit it by means of the regulator *c*.

Arrangement for Boiling and Evaporation.

Fig. 3 represents this gas furnace arranged for boiling and evaporation. *a*, is the gas-burner, Fig. 1; *b*, an iron stool with three legs; *c*, a furnace body, or iron jacket, lined with plumbago or fire-clay. Fig. 4 shows the jacket and lining in section, and marks the position of the fire-box, *d*, of the gas-burner. This furnace is 14 inches high, and 9 inches in diameter. The three brackets fixed on the upper part of the jacket serve to support the vessel that contains the liquid that is to be boiled or evaporated. A porcelain basin of 16 or 18 inches in diameter can be thus supported. It is important to allow between the jacket *c* and the evaporating basin plenty of space for the escape of the heated air, which ascends from the interior of the furnace. When the evaporating basin is of small diameter, it may be supported on iron triangles, placed in the furnace *c*. Fig. 4 shows that, around the vertical tube of the gas-burner, *a*, there is in the bottom of the furnace, *c*, a circular opening, which is of 2 inches diameter, and through which air passes freely, partly to feed the flame and partly to be heated by the flame, and be directed upwards in a continuous current upon the lower surface of the basin that is to be heated. The flame within the furnace burns steadily. No side currents of air agitate it. No part of it touches, or must be permitted to touch, the basin, which should receive its heat solely from the mass of ascending hot air. The gas-burner thus arranged, and supplied by a gas-pipe of ½ inch bore, burns about 33 cubic feet of gas in an hour, and the flame which it produces, acting upon water contained in an open porcelain evaporating basin, will heat from 60° to 212° F.,—

Fig. 3.

Fig. 4 shows that, around the vertical tube of the gas-burner, *a*, there is in the bottom of the furnace, *c*, a circular opening, which is of 2 inches diameter, and through which air passes freely, partly to feed the flame and partly to be heated by the flame, and be directed upwards in a continuous current upon the lower surface of the basin that is to be heated. The flame within the furnace burns steadily. No side currents of air agitate it. No part of it touches, or must be permitted to touch, the basin, which should receive its heat solely from the mass of ascending hot air. The gas-burner thus arranged, and supplied by a gas-pipe of ½ inch bore, burns about 33 cubic feet of gas in an hour, and the flame which it produces, acting upon water contained in an open porcelain evaporating basin, will heat from 60° to 212° F.,—

Fig. 4.

1 quart in 5 minutes
1 gallon in 15 "
2 gallons in 30 "

and when the water boils it is driven off in steam at the rate of more than a gallon of water per hour. The method is consequently applicable to distillation on a small scale, and to numerous operations in pharmacy

¹ See CHEMICAL NEWS, vol. i. p. 27, and vol. iii. p. 333.

² Fig. 2 represents a small variety of this gas-burner, in which the head is not removable, but the efflux of the mixed gases is regulated by a sliding valve, which is represented by *b*.

Arrangement for Heating to Redness a Large Fire-clay Crucible.—When a large crucible is to be heated to redness—as, for example, when oxide of copper is to be dried for use in an organic analysis,—the gas-burner is to be used without the fire-box *d*, Fig. 1, and is to be arranged with the furnace fittings that are represented in perspective by Fig. 5, and in section by

Fig. 5.

the lower part of Fig. 8, *a*, *b*, *c*, *d*. Letter *a* represents the gas-burner, Fig. 1; *b* is a tall iron stool; *c*, a chimney which collects atmospheric air to feed the flame, and leads it up close to the vertical tube *b*, by which contrivance the air is warmed and the tube cooled; *d* is a furnace-sole or plate of fire-clay; *f* is a reverberatory dome, the interior of which is best shown in the section, Fig. 6; *e* is a cast-iron ring or trivet, represented more clearly in Fig. 7; *g* is an iron chimney,

Fig. 6.

Fig. 7.

24 inches long, and 3½ inches wide; and *h*, a damper, to lessen the draught when small crucibles are to be heated. The height of this apparatus, from *a* to the top of *f*, is 24 inches; and the external diameter of the dome *f* is about 8 inches. The crucible, which may be from 4½ to 4¾ inches in height, is placed on the iron ring *e*, and

that on the clay sole *d*, and it is then covered by the dome *f*. The gas should be lighted after the crucible is placed in its position, and before the dome is put on. The dome and chimney are then to be added, and the operation allowed to proceed. With a crucible of the above size, the damper *h* is not required; but it must be used when the crucible is under 4 inches in height, otherwise the draught occasioned by extra space within the dome causes the flame to blow down. The damper must be put on the chimney before the chimney is put on the dome. The iron ring, Fig. 7, or *e*, Fig. 6, suits crucibles of different sizes, according to the side of it which is turned uppermost.

The Figures show that a crucible mounted in this furnace can lose very little heat by radiation or conduction, and hence it is that a small gas flame produces a powerful effect. In half-an-hour a 4½-inch clay crucible, filled and covered, can be heated to full redness. The progress of the ignition can be easily examined by lifting up the chimney *g* and the dome *f* by their respective wooden handles. But the action of the furnace can also be judged of by a peculiar roaring noise which it produces. If the gas and air are mixed in due proportions, the roar is regular and continuous. If there is too much gas, the roar is lessened. If too much air, the roar is increased, but is rendered irregular and intermittent. The greater the noise, the greater the heat in the furnace, but when the roar becomes spasmodic, the flame is on the point of blowing down. To prevent that occurrence, the proportion of air must be lessened or that of gas increased.

Arrangement for Heating Platinum Crucibles, as in the Fusion of Silicates with Anhydrous Carbonate of Soda.—The following arrangement is convenient when small crucibles are to be strongly heated:—Anhydrous carbonate of soda in quantities exceeding 1000 grains can be thus readily fused, and small quantities of sterling silver can be melted in a clay crucible. It is also available for ignitions or fusions in small porcelain crucibles. Fig. 8 represents the arrangement of apparatus as seen in section.

Fig. 8.

a is the gas-burner; *b*, the stool; *c*, the air-chimney; and *d*, the furnace sole, as already explained. *f* is a cylinder of fire-clay, 5 inches high, and 4 inches diameter; *k* is a plumbago or fire-clay furnace, in which is placed a small cast-iron ring, similar in form to that represented by Fig. 7, and on this ring the platinum crucible is adjusted; *l* is a fire-clay or plumbago reverberatory dome; and *g* is the chimney that forms part of the furnace represented by Fig. 5. The crucible being adjusted, the gas lighted, and the dome and chimney put on, the lapse of 12 or 15 minutes, according to the

quality and pressure of the gas, suffices for the fusion of 1000 grains of carbonate of soda in a platinum crucible.*

It will be noticed in Fig. 8 that the crucible is placed very high above the orifice of the tube *a*, at which the gas is inflamed. The distance is, in fact, about 10 inches, the point of maximum heat in the flame being at nearly that distance from the burner, more or less according to the pressure and the quality of the gas. The gas which rises from the burner *a*, though mixed with as much air as it will bear without becoming explosive when lighted, does not contain sufficient oxygen to burn all the carbon present in it. The flame produced is, consequently, quite superficial. The gaseous mixture only burns on the surface where it is in contact with fresh atmospheric air, and it requires time to take up the requisite amount of oxygen. The draught produced by the joint action of the two chimneys *c* and *g* carries the flame rapidly to a great height before the point of complete combustion is attained.

When the highest degree of heat is not required, the reverberatory dome *l* may be omitted. It must also be dispensed with when the crucible that is to be heated is of comparatively large size, because it is then liable to lower the temperature of the furnace by impeding the draught.

The effects that have been ascribed to the various arrangements of this gas-furnace can be produced with gas supplied by a pipe of a $\frac{1}{4}$ -inch bore, and at a moderate pressure, giving from 30 to 40 cubic feet per hour.

The principles of heating by gas, which have led to the construction of this furnace, may be summed up as follows:—When a crucible or other solid body is to be heated, it is to be wrapped in a single flame at the point of maximum heat, and loss of heat by radiation and conduction is to be prevented by the interposition of non-conducting materials (plumbago or fire-clay); and when liquids are to be boiled or evaporated, particularly when they are contained in vessels of glass or porcelain, the flame is to be broken up into numerous horizontal jets, and these are to be made to supply a large and regular current of highly-heated air, by which alone, and not by the direct application of the flame, the vessel that contains the liquid is to be heated. In both cases provision must be made to secure a sufficient draught of air through the furnace, because every cubic foot of gas requires for combustion 10 or 12 feet of cubic air, and the gases which have done their duty must be rapidly carried away from the focus of heat. If the steam, the carbonic acid gas, and the free nitrogen, which constitute the used up gases, are not promptly expelled, fresh gaseous mixture, in the act of producing additional heat by combustion, cannot get near the object that is to be heated, and the heat so produced out of place is wasted.

Casella's New Mercurial Minimum Thermometer.

A GOOD minimum thermometer has long been a desideratum to the scientific meteorologist. Hitherto, alcohol has been employed, but the constant sources of error arising from the use of this fluid, owing to its sluggishness, unequal expansion, and tendency to distil over into the upper part of the tube, rendered it very desirable to employ the same fluid—mercury—for registering extreme cold that is always used for estimating

heat. Several contrivances have already been suggested for effecting this object. Cumbrous arrangements of tubes were devised by men of science, which were most skilfully made by Mr. Casella, and still the difficulty remained almost as great as ever, until the construction of such an instrument was pronounced by one of the first authorities in England to be a physical impossibility.

The idea at length occurred to Mr. L. M. Casella that by a judicious adaptation of the parts of the instrument, so that the two forces, adhesion and gravitation, should be opposed to each other, the object so much desired might be attained; and, after many fruitless efforts, the application of this theory was crowned with success, and the result is embodied in the beautiful instrument now before us.

The peculiarity consists in the attractive or adhesive influence obtained by the junction of the small chamber (*a*, *b*), with the adjoining bent tube or chamber (*d*), as shown in the enlarged view (Fig. 1), the action of which is as follows:—On the instrument being set for observation, in a horizontal position, with the back plate (*e*) suspended on a nail, and the lower part supported on a hook (*f*); the bulb end may be raised or lowered, until the bent part (*d*) is full of mercury and the chamber (*a*, *b*) is quite empty; at this point the mercury in the bore of the tube indicates the exact temperature of the air at the time. On an increase of temperature the resistance of capillarity in the bore renders it easier for the mercury to expand into the small chamber (*a*, *b*) than along the narrow bore of the tube (*c*); whilst a return of cold will, for the same reason, cause its recession from this chamber only, until it reaches the flattened surface (*b*), to which the mercury adheres, as to a fixed point; when any further diminution of heat withdraws the mercury down the bore to whatever degree the cold may attain, where it remains until further withdrawn by increased cold, or till reset for future observation.

By this means, cold may be registered to any fraction of a degree observable on the most delicate standard, and no vicissitudes of climate or transit can in any way disarrange the instrument.

Solder for Brass Instruments.—An alloy of 78·26 parts of brass, 17·41 of zinc, and 4·33 of silver, with the addition of a little chloride of potassium to the borax, is recommended by Mr. Appelbaum, as the best solder for brass tubes which have to undergo much hammering or

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

*Ordinary Meeting, October 15, 1861.**Dr. J. P. JOULE, President, in the Chair.*

Mr. John Whalley was elected an ordinary member.

A Paper was read by G. V. VERNON, Esq., F.R.A.S., M.B.M.S., "*On the Irregular Barometric Oscillations at Geneva and on the Great St. Bernard, and their relations to the Mean Temperature and the Fall of Rain.*"

The object of this Paper was to deduce the effects produced upon the irregular oscillations of the barometer by considerable difference of elevation. The station at Geneva is the observatory under Professor Plantamour, and is 1335 feet above the sea. The station on the St. Bernard is the Hospice, and the observations made there are also under the direction of Professor Plantamour; its height is 8173 feet above the sea, and, consequently 6838 feet above the Geneva station.

The maximum amount of oscillation occurs at Geneva in January, and the minimum in August. The maximum at the St. Bernard occurs in December, and there appears to be two minima, one in June and the other in August.

Upon the whole, the amount of oscillation appears to diminish as the mean temperature increases, the minimum amount of oscillation occurring somewhat later than the maximum temperature.

The maximum number of oscillations occurs at Geneva in August; and there appear to be two minima, one in February and another in November. At the St. Bernard the maximum number occurs in August, and a single minimum in November.

The mean daily amount for the year at Geneva is 0.1069 inches; annual amount, 39.0719 inches: at the St. Bernard—daily amount, 0.0865 inches; annual amount, 31.5941 inches.

The total annual number of oscillations is, at Geneva, 1713; St. Bernard, 1572.

	Geneva.	St. Bernard.
Six winter months . . .	84.4 . .	76.2 . .
Six summer months . . .	86.9 . .	81.0 . .

1848 was the year of maximum oscillation, and 1857 of minimum oscillation.

A number of oscillations above the average at Geneva is accompanied by a less amount of oscillation than a number of oscillations below the average. At the St. Bernard the exact converse of this holds good.

In January, February, and December, a temperature above the average, at Geneva, is accompanied by a greater amount of oscillation than when the temperature is below the average. During the remaining months of the year the converse of this exists. For the year, a temperature below the average is accompanied by a larger amount of oscillation at Geneva than when the temperature is below the average.

At the St. Bernard, a temperature above the average, in the months of August and September, gives a larger amount of oscillation than a temperature below the average; during the other months of the year the converse of this holds good. For the year, a temperature below the average gives the largest amount of oscillation, as at Geneva.

A number of oscillations in excess of the average at Geneva, in the months of January, March, June, July, August, and November, is accompanied by a larger amount of oscillation than when the number is below the average; during the rest of the year the converse holds good. For the entire year, an increased number of oscillations is accompanied by an increased amount of oscillation.

At the St. Bernard, a number of oscillations above the

average, in the months of January, February, March, April, May, August, September, and November, is accompanied by a larger amount of oscillation than when the number of oscillations is below the average. In the remaining months of the year the converse of the above holds good. The mean of the year gives the same results as Geneva.

A rain fall above the average, at Geneva, is accompanied by a larger amount of oscillation, in every month of the year, than when the rain fall is below the average.

At the St. Bernard, a rain fall above the average, in the months of February, March, May, July, August, November, and December, is accompanied by a larger amount of oscillation than a rain fall below the average; during the remainder of the year the converse of this exists.

On the mean of the year, a rain fall above the average is accompanied by a less amount of oscillation than a rain fall below the average. This result is curious, being the direct converse of what was obtained for Geneva.

The conclusions which may be drawn from this investigation are the following. As we ascend in the atmosphere, the amplitude of the irregular diurnal oscillations of the barometer diminishes, more especially in the winter months; the summer months having an amount of oscillation not differing much from that of less elevated stations in nearly the same geographical position.

Excessive rain fall at stations of moderate elevation appears to be accompanied by a larger amount of oscillation than when the rain fall is below the average. At more elevated stations it appears as if this law was reversed, and, if found to be so, will be a very important fact.

Temperature below the average for the season greatly increases the amount of oscillation.

Report of the Committee on the Decay of the Stone of the New Palace at Westminster.

FIFTH NOTICE.

UNDER another head may be classed those processes in which hydrofluoric and hydrofluosilicic acids are employed alone or in combination with certain mineral bases. The suggestion of Professor Field and Dr. Bernays is founded on the employment, firstly, of hydrofluosilicic acid alone for the purpose of ensuring a thorough penetration of the stone, which, in the case of dolomite, is said to amount in depth to about an inch of stone penetrated in the course of half-an-hour. In the treatment of moderately compact descriptions of calcareous building-stone the hydrofluosilicic acid is applied as before, but subsequently washed over with a dilute solution of ammonia for the purpose of depositing gelatinous silica in the pores of the stone, and at the same time inducing the formation of a difficultly soluble compound, the fluoride of calcium. In the course of manufacturing the acid on any considerable scale, large quantities of flocculent silica are obtained as a secondary product, which it is proposed to economise by dissolving in potash, and using such solution in combination with the ingredients previously enumerated.

According to the degree of concentration of the acid employed, so will the effervescence, due to its action on the earthy carbonates of the stone, be more or less appreciable. Dr. Bernays prefers to use a very weak acid for the first application, and in that case the evolution of carbonic acid gas is scarcely perceptible, and cannot be supposed to present a barrier to the free absorption of the chemical agents into the substance of the block. The efficacy of the process does not appear to depend upon the production of a hard, superficial coating, but rather to encrust all the exposed faces, and to some extent even below the surface of the stone with a durable protective layer composed of

silica and fluoride of calcium in intimate union. It is asserted that the nature of these materials particularly qualifies them for resisting the action of those atmospheric influences to which dolomite seems especially sensitive. In the experiments of Dr. Bernays and Professor Field, blocks of Caen stone are described as having been taken to represent the material operated upon; but, strange to say, they make no mention of the modifications which would be introduced into the chemical reactions by the presence of the large proportion of carbonate of magnesia in dolomite—that kind of building-stone for which this special plan of treatment has been particularly devised.

In some respects similar to the foregoing is the process suggested by the Editor of this Journal. This refers to the employment of a preparation obtained by acting upon clay, kaolin, or Fuller's earth (silicate of alumina), with hydrofluoric acid. The chemical decomposition called into play when these ingredients are brought together is very complex, but we have ascertained that silico-fluoride of aluminium is formed as the chief product. The acid properties, although partly neutralised, are still capable of giving rise to an effervescence by contact with chalk; and to avoid too copious an evolution of carbonic acid from the limestone, dolomite, or other building material submitted to its action, it would in some cases be deemed advisable previously to correct any excessive degree of acidity by the cautious addition of an earthy base. A single wash merely of this solution is recommended to be applied direct to the surface of the stone. The principle upon which the employment of this compound is based cannot be fully explained while chemists are in doubt respecting the complex changes brought about by the mutual reaction between fluorine and silicon compounds with lime, magnesia, and alumina as bases. The products are, however, distinguished in all cases by their insolubility, and it is proposed to take advantage of the precipitation of such substances in the pores of stone as a means of protecting the exposed surfaces from the destructive influences of the surrounding atmosphere. According to one view, the result of employing a wash of the silico-fluoride of aluminium upon a calcareous stone will be the formation of silicate of alumina and fluoride of calcium; or otherwise if account be taken of the tendency of fluoride of aluminium to form double compounds by union with other fluorides, a kind of kryolite, in which sodium is replaced by calcium, may possibly be produced. Which ever view regarding the chemical constitution of the product be correct, it is our aim to produce through the agency of the substances described an insoluble mineral coating calculated to afford a considerable amount of protection to the surface of the stone.

A third process of the fluorine class is the subject of a provisional patent granted to Messrs. Jesse Rust and Company, who have, through the principal member of their firm and Mr. John Mossop, submitted to the Decay of Stone Committee the full particulars relating to their invention. This consists in the employment of two washes, the first an aqueous solution of caustic baryta, and the second hydrofluosilicic acid, by which double treatment the comparatively insoluble silico-fluoride of barium is formed by precipitation in the pores of the stone; or, according to a second opinion suggested by Mr. Rust, "the fluo-silicic acid combines with the baryta, forming fluoride of barium, which is insoluble in the acid itself, and the silica is set free. This being likewise insoluble, assists in closing the stone and in rendering it impervious to water." With regard to the preparation of the materials required in the process, a statement is made substantially to the following effect:—For the more economical manufacture of concentrated hydrofluosilicic acid, Mr. Rust departs from the usual system of decomposing gaseous fluoride of silicon by water. From silicate of soda he precipitates, by the addition of an acid, "free silica in the form of a pulp." By now passing hydrofluoric acid gas

through this product it is gradually dissolved, and the process is terminated when all is again taken into solution, which is much more readily accomplished than when sand is employed as the source of silica. "With regard to caustic baryta, I am making large quantities. We are glass-makers, and I take a glass pot, broken, that will not serve for glass again, clean it out thoroughly, and put in common native carbonate of baryta. I then expose it in this glass pot to the fire for various periods, say for two or three days, and it comes out perfectly caustic. Of that a great quantity is dissolved in hot water, and in operating upon the stone I use the solution hot, because a larger quantity of baryta is thereby held in solution."

Limestones coated according to the mode of treatment just now described, are said to be altogether protected from the action of weak acid; it is not stated which acid was used in the experiments, and there may be a considerable difference between sulphuric and muriatic acids in this respect; but it appears that whilst one portion of a stone which had been only partially treated was wasted away, the other (coated) portion well resisted the corrosive action. There is one circumstance which we cannot refrain from noticing in connection with the evidence offered by Mr. Rust. Whilst fully admitting the injurious effects likely to arise from the introduction of common salt into the pores of the stone, there is every probability that the method indicated for the preparation of the hydrofluosilicic acid would lead to its contamination by this or another equally injurious soda salt. The "silica pulp" would require very protracted washing to remove all the chloride of sodium adhering to it from its mode of formation, it would, in fact, be found difficult to separate the whole of the salt without sacrificing a considerable proportion of the soluble silica. All the salt left in the silica must reappear in the hydrofluosilicic acid, and consequently be eventually transferred to the block of stone.

The process of treatment suggested by Mr. Spiller, forms an isolated example of the application of phosphoric acid for the purpose of arresting decay in stone. According to this proposition, it is recommended to employ a solution of superphosphate of lime, which, applied as a single wash, has a very considerable power in hardening the exterior surfaces of all building stones that contain carbonate of lime as their principal constituent. With the object of effecting a more thorough penetration of the stone, it is in some cases considered advantageous to employ first a moderately dilute solution of the superphosphate, and to follow up this treatment with a second wash of the same, applied this time in a more concentrated form. A slight effervescence is apparent as the result of the chemical action of the superphosphate upon the carbonate of lime in the stone, and the change in the mineral constitution by which this is accompanied consists in the gradual transformation of a soluble acid phosphate into two equivalents of neutral phosphate of lime, which from their slow production and sparing solubility are separated in a crystalline condition, and go far towards filling up the smaller interstices of the stone. The porosity of a small block is shown by this means to have been diminished by about one-half; the piece of stone which originally absorbed eight per cent. of water, was after treatment capable of taking up only four and a-half per cent. From comparative experiments upon Bath and Portland stones, and upon common chalk, the increased degree of hardness becomes very apparent; the last showed this effect in the most conspicuous manner, it being found impossible to scratch with the finger-nail a surface of chalk hardened in the manner described. The action of the several corrosive agents which the treated stone is liable to encounter in the atmosphere, has not yet been fully ascertained; but so far as laboratory experiments indicate, there is every promise that a considerable amount of protection will be afforded by the coating of phosphate of lime.

CORRESPONDENCE.

On the Estimation of Nitrogen in Manures and Other Substances.

To the Editor of the CHEMICAL NEWS.

SIR,—In the CHEMICAL NEWS of October 12 are published some remarks by M. Carey Lea on my process for the estimation of nitrogen or ammonia by means of chloride of zinc.

I regret that such a task falls to my lot as that of pointing out the errors of an eminent scientific man; but, in order to vindicate myself, it seems necessary that I should do so. The process upon which he has so freely given his opinion has evidently never been tried by him, his opposition being altogether upon theoretical grounds, and by his non-practical conclusions has undoubtedly done me an injustice. He remarks, "The proposal of a new mode of analysis such as that of Mr. Walker is a new proof how much it is to be regretted that any chemist should offer a new mode of analysis without having first controlled it by the analysis of one or more specimens of substance of known composition."

I perfectly agree with him that it would be matter for regret that any chemist should propose a new mode of analysis without having done all, and even more than he suggests.

The very fact of its having been practised by me for two years before being published, is surely proof enough that ample time had elapsed to give opportunity of testing its accuracy; as, during that time, upwards of one hundred estimations were made. It did not occur to me at the time to give along with the process the comparative results, as I considered that anyone trying it would test its accuracy for himself; but, in order to satisfy the gentleman who writes against the process that he has no foundation for accusing me of such inconsistency as recommending a process as accurate without first having satisfied myself that it was so, I give a few results, copied from my analysis-book.

I have taken the results obtained by the platina process as the standard of comparison:—

No.	Superphosphate of Lime.	Ammonia per cent.	process.	
			By Zinc	By Platina
No. 1	Superphosphate of Lime.	Ammonia per cent.	0.54	0.64
" 2	"	"	0.66	0.78
" 3	"	"	0.28	0.33
" 4	"	"	0.21	0.27
" 5	Dissolved Bones.	"	2.12	2.00
" 6	Manure.	"	3.33	3.15
" 7	"	"	1.33	1.20
" 8	"	"	3.68	3.42
" 9	"	"	4.63	4.62
" 10	Hoof and Horn Cuttings.	"	14.85	14.58

Five of these analyses by the platina process (Nos. 2, 3, 4, 5, and 9), and two by the zinc process (Nos. 5, and 9) were done by other chemists.

Analytical chemists, who know the difficulty of obtaining exactly similar results, even by the same process, will agree with me that those before us show a very trifling discrepancy, and surely justify me in saying, that I was sufficiently guarded in my statements, when recommending the process, and they likewise show that no dependence whatever can be placed on mere theoretical demonstrations, such as those M. Carey Lea has treated us to; that gentleman most emphatically declares that, "The necessary result must be an under-estimation of the ammonia, leading to errors of such magnitude as would render the process wholly unfit even for the roughest technical analysis."

It is a pity that he should have committed himself in

this way, as I can most emphatically assert that an under-estimation of the ammonia is quite exceptional, and when it does occur is mostly with substances very poor in ammonia, and even then of comparatively trifling amount: the tendency of the process is rather to slightly over-estimate it, taking as the standard of comparison the results obtained by the platina process.

Following up M. Carey Lea's process of reasoning, he takes a neutral solution of chloride of zinc, adds one drop of ammonia which occasions a precipitate, then adds, I presume, about a thousand drops of solution of chloride of ammonium when the precipitate is re-dissolved. True enough all this occurs; but why add solution of chloride of ammonium? it forms no part of the process recommended by me. This experiment appears to be the sum total of evidence against the process and should only pass for what it is worth. It comes to this: To what extent is oxide of zinc soluble in chloride of ammonium? I would have liked very much had M. Carey Lea informed us. His remarks made me curious on this point especially as the practical results do not at all agree with his theory, and I have consequently made some experiments with the view of answering the question. I took three equal quantities (Nos. 1, 2, and 3) of a solution of chloride of zinc specific gravity 1.012 and to each added equal quantities of solution of pure caustic ammonia. From No. 1 I collected the precipitate, washed, dried, ignited, and weighed. I found the weight to be 6.15 grains. From No. 2 I collected the precipitate and washed thoroughly. I then made a hole in the filter and washed the precipitate into an empty test glass, then added a solution of chloride of ammonium of known strength agitating the mixture well upon each addition until only a slight trace of the precipitate remained undissolved. By this method I ascertained that it required 450 grains of chloride of ammonium to dissolve 6.15 grains of oxide of zinc. To No. 3 I added solution of chloride of ammonium of the same strength as that added to No. 2, and found that it required 560 grains to dissolve 6.15 grains of oxide of zinc.

The solution of chloride of ammonium contained 100 grains per alkalimeter, and had a sp. gr. of 1.03. From these results may be deduced what influence the presence of chloride of ammonium will have in the analytical process, and as the oxide appears to be less soluble in a mixture of chloride of zinc and chloride of ammonium than in chloride of ammonium alone, it is but fair to test it by that standard.

The average amount of ammonia contained in manures is about 3 per cent., and 30 grains are generally taken for an analysis; this will produce a precipitate of oxide of zinc weighing 2.14 grains, and chloride of ammonium in solution weighing 2.82 grains, which will dissolve 0.03 of a grain of oxide of zinc equal to 0.04 per cent. of ammonia.

This trifling discrepancy surely cannot be enough to stigmatize the process as "grossly inaccurate," as often far greater differences are observable when two analyses of the same substance are made by the platina process, which as far as I can learn, is generally considered to be very accurate although tedious.

I have only, in conclusion, to reiterate my former statement made nearly twelve months ago, with this difference, that I have practised the process for nearly three years instead of two, and as it gives accurate results, I can with confidence recommend it.—I am, &c.

JAMES WALKER.

Crawford Street Chemical Works, Glasgow.

Estimation of Alcohol in Wine.

To the Editor of the CHEMICAL NEWS.

SIR,—In your last Number Mr. Horsley gives a method of determining the alcoholic contents of wines, which, from the absence of any acknowledgment, I infer he wishes

to pass off as his own. It should be known, then, that this method is to be found at page 157 of the translation of Mulder's "Chemistry of Wine," by Dr. Bence Jones. It was given, you may remember, at page 36, vol. 1 of the CHEMICAL NEWS, and excited some discussion at the time.

I am, &c.

SUUM CURIAUX.

P.S.—The special application is, of course, Mr. Horsley's. October 24.

Quality of Water at Leeds.

To the Editor of the CHEMICAL NEWS.

SIR,—I have been given to understand that some of the waters supplied to Leeds or its vicinity, and used for dyeing and other similar purposes, are so impregnated with iron as to be very objectionable. Could you or some of your readers inform me what are the sources of the Leeds water supplies, which of them furnish water containing iron, what analyses have been made of the latter, and what are the means used (if any) to get rid of the impurity in question?—I am, &c.

J. B. M.

MISCELLANEOUS.

Chemical Society.—The first meeting of the season of this Society will take place on Thursday next, November 7, at Burlington House. Chair to be taken at 8 p.m.

Nitrates in Well-water.—In reference to Dr. Haince's paper on "Nitrates," the following analysis of a well-water at Tewkesbury, analysed by Herapath, has been forwarded to us:—

Chloride of calcium . . .	37.02
Nitrate of lime . . .	45.06
" potash . . .	42.09
Sulphate of soda and magnesia .	86.97
Chloride of sodium . . .	21.76
Carbonate of lime and magnesia	73.30
Sulphate of lime . . .	40.09

Photo-Electric Apparatus.—A Trappist named Delatol-Sevin, of the Abbaye de la Grâce-Dieu, has invented a new pile, much stronger, and at the same time much cheaper, than the pile of Bunsen. By means of his photo-electric apparatus he produces an electric light as cheap as gas, and with his thermo-electric pile he supplies calorific on economic terms hitherto unknown. Several of these apparatus have been constructed, and one is at full work in the Abbaye of La Grâce-Dieu. Manufactories for the public are shortly to be established in Paris and at Lyons. The apparatus for producing gas will not be given to the public until after the Exhibition at London next year, but that for heating buildings will be made public on the 16th of December next. The inventor has been authorized to make public experiments with his system of lighting on the Place Saint Jacques in Paris, and on the Place Bellecourt at Lyons.

Curious Lunar Phenomenon.—F.M., writing from High Wycombe, on the 17th October to the *Morning Star*, says, "Can I claim a corner for the following account of a remarkable and extraordinary appearance I witnessed on the disc of the moon on the night of the 14th, about nine o'clock, with an achromatic telescope, magnifying power about 170? In examining the cup-like cavities situated near the bright spot Kepler, on the irregular edge of the planet, I observed four smaller spots, in the shape of an irregular square, standing out in bold relief in the dark sky, surrounded by or emitting a beautiful prismatic luminous light, twinkling like the bright star Sirius. Having from time to time observed the moon

pretty nearly in all its phases, I never saw before the cup-like cavities of that orb as I did then, and in that particular spot, sparkling like some variegated coloured gems. At the time I could not account for it. I thought probably my glass deceived me; but recollecting that it was a pure achromatic lens, free from colour, I could not come to any other conclusion than that the spectacle was four active volcanoes in operation. The luminous light I observed was the reflection of external fiery matter pouring down the sides of the central mountains out of the mouth of the volcanoes. I merely state what I saw, and venture my humble opinion, subject to correction, drawing my conclusions. I always supposed the moon devoid of an atmosphere, but if the above, as I assume, were volcanoes, as a matter of course taking that body to be of the same organisation and the same matter as our earth, an atmosphere must be necessary for combustion in that body as well as for the latter. Perhaps, Mr. Editor, some of your numerous readers can explain the phenomena I witnessed."

Discovery of Gold in the Valley of the Saskatchewan.—Mr. A. K. Iebister, author of a paper on the Hudson's Bay Territories, says:—"I have just received a letter from the Red River colony, in the Hudson's Bay territory, announcing the discovery of a valuable gold field by a party of American miners from California, on the north branch of the Saskatchewan. This intelligence I see confirmed in recent papers published at St. Paul's, Minnesota, and it may therefore be relied on as accurate. Two gentlemen from California have recently arrived in that town with a considerable quantity of gold collected by themselves along the upper waters of the Saskatchewan, and they describe the yield and quality of the metal as promising to be quite equal to that of British Columbia, which I need hardly say occupies the opposite flank of the Rocky Mountains, and may therefore reasonably be inferred to be of a similar geological character, while we know that it is watered by streams which have a common origin in the same auriferous range with the northern tributaries of the Saskatchewan."

Action of Poison on Wild Animals.—For the purpose of poisoning them strychnia is used. I have tried aconitine, atropine, and corrosive sublimate without success. The two former may not have been pure enough, though I obtained them from the first chemical works in England and at a very high price. The only poison that I have found strong is strychnia. One or two grains of this are mixed with a little tallow, forming a small ball, and covered with a coating of grease outside to prevent the animal from tasting it. A quantity of pounded dried meat and morsels are strewn about so that the animal after swallowing the poison may be detained a sufficient time for it to operate. The distances which animals go before they die vary greatly; in some instances they fall directly, in others they run several miles with the same dose, and arranged in like manner. This I attribute to several causes; to their fatness, and to the quantity of food in their stomachs, as lean and hungry foxes die much more quickly than others. The medium in which the poison is given also causes a great difference. When put up in fresh meat a very long time elapses before it operates. Wishing to preserve a specimen of the Hare-Indian dog for the Smithsonian Institution, I resolved to kill the animal by poisoning. Two grains of strychnia of the first strength were administered in a piece of fresh meat; at the end of two hours the animal was as well as ever. I then administered one grain more mixed with grease, in two minutes the spasms began, and in five the animal was dead. The first symptoms were a restlessness and contraction of the pupil of the eye, and a flow of saliva from the mouth, violent cramps then ensued, the head shook violently, like a paralytic person, the legs were drawn up,

and the spine took a circular shape, a lull of a few seconds then ensued, when after an attack of great violence the animal died. On dissection the blood vessels of the head and neck were found very full of black and clotted blood, such as I have seen in the jugular vein of a person who had died of apoplexy. There was no inflammation of the stomach, and the fatal bait was found in the throat entire. Once seen, the symptoms of poisoning by strychnia are easily recognised, and I would be certain now of passing a correct opinion on a case of the kind. Dogs take a longer time to expire than either wolves or foxes; the latter dying most quickly; in fact according to the ratio of the wild nature of the animal who eats it will be the quickness and violence of its death.—B. R. Ross, in the "*Canadian Naturalist*."

On the Natural Dissemination of Gold.—Mr. Eckfeldt, the principal assayer of the United States Mint at Philadelphia, has lately made several interesting examinations tending to show the very wide distribution of gold. Passing over the evidence respecting its presence in various galenas, in metallic lead, copper, silver, antimony, &c., we recite the following, perhaps the most curious result of all:—Underneath the paved city of Philadelphia there lies a deposit of clay, whose area, by a probable estimate, would measure over three miles square, enabling us to figure out the convenient sum of ten square miles. The average depth is believed to be not less than fifteen feet. The inquiry was started whether gold was diffused in this earthy bed. From a central locality, which might afford a fair assay for the whole, the cellar of the new market house in Market Street, near Eleventh Street, we dug out some of the clay at a depth of fourteen feet, where it could not have been an artificial deposit. The weight of 130 grammes was dried and duly treated, and yielded one-eighth of a milligramme of gold; a very decided quantity on a fine assay balance. It was afterwards ascertained that the clay in its natural moisture loses about fifteen per cent. by drying. So that, as it lies in the ground, the clay contains one part gold in 1,224,000. This experiment was repeated upon clay taken from a brickyard in the suburbs of the city, with nearly the same result. In order to calculate with some accuracy the value of this body of wealth, we cut out blocks of the clay, and found that, on an average, a cubic foot as it lies in the ground, weighs 120 pounds, as near as may be; making the specific gravity 1.92. The assay gives seven-tenths of a grain, say three cents' worth of gold to the cubic foot. Assuming the data already given, we get 4,180 millions of cubic feet of clay under our streets and houses, in which securely lies 126 millions of dollars. And if, as is pretty certain, the corporate limits of the city would afford eight times this bulk of clay; we have more gold than has yet been brought, according to the statistics, from California and Australia. It is also apparent that every time a cart-load of clay is hauled out of a cellar, enough gold goes with it to pay for the carting. And if the bricks which front our houses could have brought to their surface, in the form of gold leaf, the amount of gold which they contain, we should have the glittering show of two square inches on every brick.

ANSWERS TO CORRESPONDENTS.

Gum Water.—W. C.—The best receipt with which we are acquainted for good gum water which will not crack off nor turn sour is:—Best gum arabic, half pound; loaf sugar, 8 medium sized lumps; creosote, 5 drops; water, to make up the bulk to 20 fluid ounces.

Des Cartes' Principia.—A. K. K.—We have not met with an English translation of this work.

J. Walker.—Received with thanks.

Mr. Bowditch.—The slip is received with thanks. It is very interesting, if true.

E. B.—In our previous Numbers.

Books Received.—Elementary Treatise on Physics, by Professor A. Ganot. Translated and Edited by E. Atkinson, Ph.D., F.R.S. Part I. London: H. Baillière, Regent Street. "The Canadian Naturalist and Geologist" in exchange.

Technologist.—Next week.

the chloride of copper, either by dissolving the oxide of copper or the native carbonate in hydrochloric acid, or by double decomposition with sulphate of copper, chloride of barium, &c. &c. Evaporate and crystallise the solution of chloride of copper thus obtained, mix it with sand, and dry it absolutely (probably in a reverberatory furnace). Introduce the dried mixture into retorts similar to those employed in the manufacture of gas. If these retorts are of cast-iron, they should be covered with a coating of earth mixed with charcoal, to isolate the metal. The chloride, greatly heated, decomposes into chlorine and sub-chloride.

The protochloride, the residuum in the preparation of chlorine, is not lost; it may be reconverted into chloride by the oxidising action of the air in presence of hydrochloric acid. The reconverted chloride is treated in the way just pointed out; and so the circle of reactions go on indefinitely.

It will be seen that this process corresponds with that of M. Dunlop-Tennant. It is atmospheric oxygen which, by reproducing bichloride of copper in this process, and binocide of manganese in Tennant's, effects the oxidation of the hydrochloric acid. The advantages of M. Laurens' interesting reaction are the following:—A saving of half the hydrochloric acid, and regeneration of the comburant by a direct and single operation. The objections to the process are the dearth of copper and the many chances of loss of the metal, either as chloride during its decomposition, or of protochloride or chloride in some of the unavoidable removals; moreover, it is to be feared that handling large quantities of chloride of copper the dust arising from it in a chlorine manufactory would be likely to injure the workmen's health. In any case, this interesting process is highly to be recommended for laboratories, for furnishing dry chlorine readily, without the intervention of a fragile and cumbrous apparatus.—*Rép. de Chimie.*

TECHNICAL CHEMISTRY.

On the Induration and Preservation of Stone,
by Messrs. BARTLETT BROTHERS and Co., Camden Town.

AMONGST the many efforts to effect the preservation of stone, we respectfully ask you to chronicle our own in the pages of your journal. It would ill become us to disparage other processes, or attempt to laud our own invention in your columns. We propose, therefore, to confine ourselves to a full description of the invention, the materials we use to accomplish our end, and the behaviour of these materials separately and in combination. Enough has been said in this journal to show, from logical and chemical reasoning, that silica must form a principal feature in all efforts to produce an eligible material for purposes of induration. Silica, then, is the principal material in our process, and that in the form of silicate of potash. Of this material in itself we need say but little; but, lest silicate of soda and potash should here be deemed synonymous, we would anticipate our remarks by saying that in this process they are by no means identical, the silicate of soda producing results both unsatisfactory and valueless. The second material is the aluminate of potash. Of this, in the form of an aqueous solution, we find it stated by all chemical authorities to the present time that it precipitates an hydrate of alumina, difficultly soluble in excess of the precipitant; and thus we found it behave after forty-eight hours, precipitating most bulkily in heavy solutions, and as much so in proportion

in light specific gravities. We need not say how valueless was such a solution commercially, nor tell the difficulties attending the discovery of a simple remedy, so simple as the determination of the particular specific gravity at which it would not precipitate. The behaviour of the aluminate with water is remarkable, seeing that one atom of alumina held in perfect solution by say three atoms of water should be precipitated by the addition of a fourth, or by the withdrawal of one of the three atoms. Such facts we leave to the investigation of those who may be pleased to pursue them further. Suffice it to say, then, that the aluminate used is prepared from a fused compound of alumina and potash, which product, being highly deliquescent, is easily soluble in water, and so nearly neutral as to contain in its best form of manufacture but two per cent. of free potash.

In the combination of silicate of potash and this aluminate of potash consists the process, the consideration of which affords some most interesting details. When silicate of potash, sp. gr. 1.250, and aluminate of potash, sp. gr. 1.200, are mixed together, an instantaneous decomposition takes place, and the result is a solid mass, consisting of silicate of alumina and some free potash. This hardens with extraordinary rapidity, and is a most beautiful example of the great affinity of silica for alumina. But take a solution of a lighter specific gravity, and we find that decomposition does not instantaneously take place. On the contrary, the liquidity of the two solutions in combination is retained for a time, only, however, proportioned to the quantity of water with which it is diluted. Thus a specific gravity of 1.150 will last as a solution ten hours, while at 1.200 it solidifies immediately. The cause of this arrest of the decomposition—if, indeed, it is arrested—and the peculiar part the water plays in this interchange of elements, will yield a field of interesting inquiry. With the results, however, we have now more immediately to deal; and

Firstly, the time so necessary for manipulation is given in the use of these materials which in themselves secure an insoluble product by their mutual decomposition. Secondly, that the agent and re-agent being mixed in one solution, there can be no fear of the one or the other being in excess or unneutralised, as in the use of acid or second solutions. Thirdly, the product resulting from this combination of silicate of potash and alumina is insoluble in dilute sulphuric and hydrochloric acids. And lastly, if Ansten, Bath, and Caen stone or chalk be pounded, this product will recombine them, thus showing that its chemical affinities are in favour of the material with which it is proposed to impregnate the stone. Finally, in the works of Fuch's and the brochures of Kühmann the foreshadowing of this process may be seen; and in the Report of the Commission appointed to investigate the causes of the decay of the Houses of Parliament, there are mentioned, though not in conjunction, the very materials proposed to be used by this process. We trust that our researches in this direction may prove so successful as to benefit the public at large, and afford its quota of like satisfaction to ourselves.

Sugar in the Urine of the Fox.—It will be of some interest to physiological chemists engaged on the hepatic and sugar question, to learn that De Vintschgau (*Sitzungsber. der K. Akad. der Wissenschaften zu Wien*, Bd. iii. s. 523) has found small quantities of sugar in the urine of the fox, a purely carnivorous animal. The method he used to detect it was that of Brücke.

PHARMACY, TOXICOLOGY, &c.

On the Analysis of Stains, supposed to be caused by Blood, by THOMAS D. TOASE, Esq., F.C.S., F.S.A., Jamaica.

It is a matter of the highest importance to know if stains, supposed to be caused by blood, can be correctly analysed; and also if it can be determined what animal the blood came from, but more especially if it is human blood. These questions generally bear reference to judicial cases, and often involve a matter of life or death.

It is the more necessary to examine these questions, as certain authorities have asserted that not only can blood stains be analysed correctly, but that even the animal from which the blood came can be firmly established.

I will examine, one by one, the tests given us by these authorities.

If the spots are upon some fabric, they must be cut out, but if not, they must be carefully scraped off. In either case, they must be placed in some clear water, keeping the spots in the water, but near the surface. If these spots are blood spots, a heavy stream will fall to the bottom of the water. This is the method given by my late much lamented master, M. Orfila, the celebrated toxicologist. I mention this, as Dr. Taylor, in his late work on Medical Jurisprudence, would seem to take the credit to himself of originating this simple mode.

Supposing that the heavy stream falls, there is certainly an indication of blood; but if there is no stream, an indication of the presence of blood is wanting, chemically speaking.

If the heavy fluid is formed, then take the pieces out of the water carefully: draw off the supernatant water with a pipette, so as to leave only what may be presumed to be blood; with care this can be easily managed (Orfila). Put this fluid into six test-tubes, and a portion on a glass slip to be examined later under the microscope; these portions to be tested in the following manner:—

The quantities, of course, are so small that it would be useless to examine the spots for fibrine, important though such an examination would be, if possible. On an average, in a healthy body, blood is said to contain only two parts in a thousand of fibrine. Seeing the smallness of the quantities, the attention of the analyst must be directed to the albumen and the iron. It will be useless to seek for the characteristic colouring matter of the blood (hematosine) after the lapse of some days, these spots being, in all probability, several days old before they pass into the hands of the analyst.

Before examining the tests, I must draw special notice to this fact, in the two tests I shall first mention, the spots must be fresh, as these two tests do not show themselves on blood that has been kept for some time. Indeed, in one case mentioned by Mr. Taylor, some true spots of blood which had been operated upon, refused to answer to these two tests after twenty-four hours in warm weather. I shall, however, mention them:

1st.—If the stains are recent, take a little of the red fluid that has been collected, and mix it with some water; if this fluid dissolves readily in the water, and impart to it a rich red hue, the colouring matter of blood (hematosine) is indicated. I cannot but consider this test as valueless, not only because freshness is a necessity, but because other colouring matter may pro-

duce the same tint when dissolved in water, and the supposed blood-stains may be only stains produced by other colouring matter, not hematosine.

2nd.—To this solution add a few drops of weak ammonia, taking special care to add very little ammonia (a glass rod dipped in a weak solution of ammonia, shaken and dipped in the red solution, will be the safest). If the red solution becomes crimson or green, it is not blood; but if the solution remains unchanged, then the evidence is still stronger that this colouring matter is the hematosine of blood. This is certainly a most valuable test, if there are no red colouring matters, other than hematosine, which are unaffected by ammonia.

But I cannot dwell too strongly on the fact, that these two tests, indicating the presence of the colouring matter of blood, require that the stains be fresh.

In the following tests freshness is not necessary.

3rd.—Take some of the thick liquid, collected from the stains; add a quantity of concentrated ammonia, and see if the colour now changes to a brown tint; if so, I think we have reason to suspect iron, but we are far from having established its presence, to prove which we must apply all the known tests for iron, which our small quantities to be tested will not allow. We must, therefore, rest contented with a mere indication. And even should we determine the presence of iron in the stains, that would not prove, of itself, that the stains were blood-stains. It is evident that this test possesses but little value, seeing that we can produce the same reaction from other stains besides blood-stains.

4th.—Boil a little of the red fluid, and see if it coagulates, if the colour is destroyed, and if a flocculent brown precipitate is formed. The coagulation will indicate albumen, but that is all.

5th.—Take the flocculent brown precipitate, filter and dry it, and see if it becomes a black resinous substance, insoluble in water; if so, then add some caustic potash, boil again, and see if a green coloured solution is formed. This would lead us again to suspect iron.

6th.—Now take some of the suspected fluid, add to it some strong nitric acid, and if the fluid coagulates albumen is again indicated.

But I must protest against these tests; they are un-chemical and unsatisfactory; we can obtain from them, at most, but indications of iron, albumen, and, if the spots are fresh, hematosine. I have purposely employed the term "indications," for I most emphatically assert, that no chemist has a right to say "such and such is the composition of such a body," if each material composing that body has been determined on the faith of one or two tests, and these tests the very reverse of conclusive; such reasoning could not be admitted in a chemical laboratory. As an analytical chemist, I would not do so in any commercial analysis, fearing a mistake on my part, leading to future exposure by some brother chemist, as in a case I well remember: a chemist had relied on two tests, and on them determined that a certain substance contained lead; another chemist examined the same substance more carefully, and found that it contained bismuth, and not lead. If a chemist dreads the exposure of a mistake, caused by an incomplete analysis of a mere commercial substance, how much more would he fear swearing a fellow creature's life away on mere indications?

For I assert, that to make a complete analysis of a fluid, suspected to be blood, that the iron, the albumen, the hematosine, and the fibrine should each be separated and each examined by all the known tests for each; and

if one test fails, I maintain that the analysis is incomplete, according to laboratory practice.

But there is another important aid, the microscope, which determines the presence and the form of the corpuscles, if present, this is a most valuable test; but it is simply a microscopical test, unsupported by a satisfactory chemical analysis.

I, therefore, come to the conclusion that, considering the small quantity of matter to be acted on, we can only obtain presumptive evidence that blood is the cause of these stains. I must again remind the reader that the determination of these questions may involve a matter of life or death, and that the accused has a right to the benefit of a doubt, the more especially as such an examination as I have just described, made in a chemical laboratory, where only commercial interests are concerned, would not be received.

I am loath to leave this subject without giving a striking proof of how elementary our knowledge of blood is. Fowne's work on Chemistry, a text book in very general use, contains this assertion:—"The colouring matter of blood contains albumen, and coagulates by heat, and by the addition of alcohol; this albumen cannot be separated, and all attempts to isolate the hematine, or red pigment, have consequently failed. From its extreme susceptibility of change nothing is known of it in a state of purity." Now, Muller, in his "Manual of Physiology," says quite the reverse:—"When blood, coagulated by alcohol, is boiled in this re-agent, the hematine is dissolved, and we thus succeed in freeing it from the whole of the adherent albumen."

We have now to determine if human blood, submitted to a microscopic examination, can be distinguished from the blood of any other animal. The circular form of the globules confines our attention to mammiferous animals, to the exclusion of the dromedary and the llama. This subject has already been so satisfactorily discussed by Taylor, that I cannot do better than subjoin the following quotation:—"The only microscopic distinction between the blood of man and domestic animals, consists in a difference in the size of the blood globules. This, however, is only an average difference, for the globules are found of very different sizes in the blood of the same animal. In making use of this criterion, it would be necessary to rely on the majority of the corpuscles seen in a given area, and under the same power of the microscope. The corpuscles in man, the dog, the rabbit, and the hare, are nearly of the same size. In the blood of the sheep and goat, they are smaller than in that of any other animal. According to Gulliver, the measured diameter of the globules in human blood varies from $\frac{1}{1000}$ th to $\frac{1}{2000}$ th of an inch. From the examination of various specimens of human blood, I (Taylor) have found the average diameter of the globules to be the $\frac{1}{1500}$ th of an inch, the maximum size being the $\frac{1}{1000}$ th and the minimum $\frac{1}{2000}$ th. According to Gulliver, $\frac{1}{1500}$ th in the ox. In the cow, according to my measurement, $\frac{1}{1000}$ th to $\frac{1}{1500}$ th. In the sheep, according to Gulliver, $\frac{1}{1500}$ th; according to my measurement, $\frac{1}{1500}$ th to $\frac{1}{2000}$ th. In the goat, according to Gulliver, $\frac{1}{1500}$ th.

"These measurements apply to recent blood, which has not been allowed to dry in animal and vegetable stuffs. In this case a distinction might be made between the blood of a human being and the sheep. When blood is dried on clothing, and it is necessary to extract the corpuscles by means of a liquid of a different nature from the serum, we cannot rely on slight fractional differences, since we cannot be sure that the globules,

after having been dried, will ever re-acquire, in a foreign liquid, the exact size which they had in serum. Medical evidence must, therefore, be based, in such cases, on a mere speculation."

Many other considerations might be added, but they appear superfluous after the very conclusive summary I have just quoted.

NOTICES OF BOOKS.

Report of the Committee on the Decay of the Stone of the New Palace at Westminster.

SIXTH NOTICE.

THE processes which have been submitted to the Decay of Stone Committee naturally arrange themselves under two distinct classes, those which have for their object the production of a mineral coating upon the surface of the stone, and secondly, those in which the protective agent belongs to the organic division, and consists either of bituminous or oleaginous materials alone, or applied in combination with but small proportions of mineral ingredients. In the course of our previous notices we have briefly described all the suggestions and proposals which come within the first or mineral division. It remains, therefore, to proceed to the consideration of some five or six processes in which materials are employed, all of the organic class, but differing very considerably in regard to their probable power of endurance. The chemists on the Committee, in their report of June 17, have been careful in distinguishing between the properties of certain organic substances, which, although they may fall under the same natural division, exhibit, nevertheless, very different characters. In reference to this point, they aptly remark, that "of the second division of processes—namely, those which are only calculated to afford protection of a temporary character—we would recommend that, in addition to the experiments already made in this direction, further trials be instituted of some of the more promising materials of this particular description. This recommendation is based upon the consideration that substances included under the appellation of Organic differ essentially in their powers of resisting the destructive action of the atmosphere. Who ever is acquainted with the nature of organic substances cannot fail to appreciate the different degrees of stability under atmospheric influence exhibited by gluten, gelatin, or starch (which we find enumerated among the proposed protective agents), and by bees' wax and paraffin, not to speak of many of the fossil gums, which exhibit a degree of permanence approaching that of mineral substances. The materials which we would recommend for selection to be tried in comparison with linseed oil are paraffin, bees' wax, and some of the more permanent gums and resins, applied in the form of solutions in volatile solvents."

Of these processes, the first which received application to the Houses of Parliament was the "patent vulcanising and preserving process" of Mr. Daines. This mode of treatment consists in applying a mixture of linseed oil and sulphur, which is merely brushed over the surface of the stone, three or as many as five coats being given according to circumstances. The sulphur does not appear to be employed in larger amount than is capable of dissolving in the oil, so that none is actually laid on the stone in the solid form. A certificate to this effect, signed by Mr. Dugald Campbell, is handed in as part evidence. This document tends to show that the sulphur is not merely deposited on the surface, but penetrates the substance of the stone fully as deep as the linseed oil; that, in fact, no separation of ingredients occurs.

As an indication of the early period at which the Westminster Palace showed the first signs of decay, it is important to note that the sanction of Sir Charles Rennie

having been obtained, Mr. Daines commenced his operations upon the building as far back as the year 1854, "shortly after the execution of the masonry, and when it was quite clean." A comparison of the work coated at that time or soon afterwards with other portions of the exterior not so protected, forms the subject of a favourable report signed, among other architects, by two members of the present committee, by Dr. Rutledge, and by Mr. Edward Macmurdo, chemist, of the firm Davy, Macmurdo, and Company.

The general appearance of the prepared surfaces of stone is said to be cleaner and brighter than the adjacent untouched portions of the work. In one part only—that first treated—an unsatisfactory discoloration is complained of; this is, however, sought to be explained by the circumstance that "the American potash used in cleaning the surface had been mixed in new oak pails." In reference to this preparatory treatment, we cannot but think that the use of a material which would have a tendency to impart to the stone surfaces a deliquescent character, was highly injudicious, and that such a step would be calculated to prevent that thorough contact and penetration of the stone by the preservative agent which must be the chief aim of this and similar processes. As the only further subject of remark which occurs to us to mention in regard to Daines' process, is the well ascertained property of sulphur, when in a finely divided condition, to undergo oxidation, becoming converted, indeed, into nothing short of sulphuric acid by exposure to the atmosphere. Flowers of sulphur when tested with moistened blue litmus paper, will always be found to communicate an acid reaction, and water filtered through them will usually afford with chloride of barium an immediate indication of sulphuric acid. Now, as the general result of the chemical examination of the efflorescent matters which are constantly forming on the decayed surfaces of dolomite was shown by Mr. Warrington (*vide* Mr. Ransome's evidence) to consist of 90 per cent. of sulphate of magnesia, and only small quantities of the sulphates of lime and soda, it must, we think, be in every way an unsatisfactory proceeding to apply to the stone of the Houses of Parliament that substance which when oxidised, is known to be peculiarly active in inducing disintegration. The presence of linseed oil, though it may lessen, is not likely to overcome altogether this tendency of sulphur to undergo oxidation.

A Manual of Chemistry, Descriptive and Theoretical. By WILLIAM ODLING, M.B., F.R.S. Part I. London: Longman and Co. 1861.

SECOND NOTICE.

In a former number we noticed the chief characteristics of Mr. Odling's Manual; we now propose to criticise with greater fulness, not so much the Author's method of handling his subject, as some of the more novel or striking of his views and statements,—those, in fact, which point out the work as no ordinary production. The Author, indeed, fully acknowledges his obligations to previous writers who have adopted the Unitary Notation; such, for instance, as Laurent, Gerhardt, Kekulé, and Hofmann. While he has elaborated, supplemented, and modified the general theory of the first-named chemists, he has applied several of the happy suggestions of the Belgian Professor to that department of the science generally known as inorganic chemistry. But, after all, the work is marked by great originality, and we heartily welcome the first instalment of it as a most important addition to the chemical literature of the country. The book is so well and clearly written, and is evidently the result of so much honest labour and careful thought, that it is very difficult to discover any flaw at all in it. If we were called upon to point out what we considered defects, we could cite

nothing but a slight vagueness occurring occasionally in the description of reactions, or of manufacturing processes. The book also is scarcely suited for the beginner; it plunges too precipitately into the arcana of the science. But the system of the book is so truly scientific, the style so attractive, and the advocacy of the new notation so earnest and consistent, that the most practised chemists cannot fail to be interested in its perusal.

The method of describing the elements, according to their relations to the typical element, hydrogen, is now applied to general chemistry by Dr. Odling. Professor Kekulé had already shown how admirably it was calculated to throw light upon the constitution of many organic bodies, hitherto regarded as anomalous. Professor Odling has found suitable places for many compounds generally viewed as of uncertain formulae or doubtful relationship. For example, some of these are now viewed as aldehydes, and as bearing the same relations to their respective oxacids as common aldehyde bears to acetic acid. They are for the most part known in the form of chlorine substitution-products, and although these have been in some cases obtained from the original aldehydes by replacement of chlorine for hydrogen, yet they are usually formed by indirect processes. When the chlor-aldehydes react with water, a characteristic result follows. They exchange Cl for the compound radicle, HO, so as to form HCl and the normal oxacids to which they correspond. Among such aldehydes the following bodies occur:—

Sulphurous chlor-aldehyde,	Cl ₂ SO
(Bichloride of thionyle).	
Sulphuric chlor-aldehyde,	Cl ₂ SO ₂
(Bichloride of sulphuryle).	
Phosphorous chlor-aldehyde,	Cl ₂ P
(Terchloride of phosphorus).	
Phosphoric chlor-aldehyde,	Cl ₂ PO
(Oxychloride of phosphorus).	
Sulpho-phosphoric chlor-aldehyde,	Cl ₂ PS
(Sulpho-chloride of phosphorus).	

The radicles thionyl and sulphuryle appear again in the bodies known as thionamide and sulphamide;—

Thionyle-diamine	(SO)"H ₂ N ₂
Sulphuryle-diamine	(SO ₂)"H ₂ N ₂

The curious substance discovered by Williamson, namely, chlorhydrosulphurous acid, H Cl SO₂, is viewed as intermediate between the corresponding chloraldehyde and the biatomic acid, the sulphurous.

Nitric chloraldehyde is ClNO₂, and may of course be viewed also as chloride of nitryle. Nitrous chloraldehyde is ClNO, and also takes its place among the other azotyle compounds in the following series:—

Chloride of azotyle,	(NO) Cl
(Chloro-nitrous gas).	
Bichloride of azotyle,	(NO) Cl ₂
(Chloro-nitric gas).	
Sulphate of azotyle,	(NO)HSO ₄
Nitrous acid,	(NO)HO
Nitrous anhydride,	(NO) ₂ O

We find a judicious view of compound radicles which the author describes as not necessarily existent in bodies, but as molecular groupings capable of being transferred from one body to another. By accepting this modified doctrine we shall still be able to regard bodies as related to one another in constitution, when they are known to be related to one another in derivation and behaviour.

By an enlargement of the ordinary idea of double decomposition, the author is enabled to refer most chemical changes to that symmetrical mode of action. Such changes are the direct union of two elements—the breaking up a compound into its elements—and the liberation of a single element in the free state.

The author illustrates the relation of seriated heterology

THE CHEMICAL NEWS.

VOL. IV. No. 101.—November 9, 1861.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Presence of Vanadium in an Aluminous Mineral from the South of France, by M. H. SAINTE-CLAIRE DEVILLE.

IN June, 1858, M. Meissonnier, engineer at the mines at Marseilles, sent me some specimens of an iron mineral which was very difficult to treat on account of the infusibility of its slag. This substance, obtained from Baux, near Arles, consisted of small round grains buried in a perfectly crystallised pure limestone.

The analysis which I made of it, after having separated the limestone with weak hydrochloric acid, gave me the following results:—

Alumina	55.4
Oxide of iron, carbonate of lime, and water	44.6
	100.0

I then recognised it as the mineral to which M. Berthier gave the name of Bauxite. It is a hydrate of alumina which M. Dufrenoy has ranked with gibbsite, or rather diasporé. The analysis of M. Berthier, performed on a mineral from Baux, gave him the following figures:—

Alumina	52.0
Oxide of iron	27.6
Water	20.4
Chromium	traces
	100.0

It is very true that fused alkalis become coloured yellow when heated with bauxite, but we shall see a little further on that the colouring matter in this case is vanadium, and not chromium.

From other specimens of this curious substance which M. Le Chatelier found in the Departments of Gard and Var, where it is very common, we found that we had met with the richest mineral of alumina that had yet been discovered. Indeed, some specimens contained as much as from 60 to 65 per cent. of alumina.

The plan which I at first adopted to dissolve this mineral is very simple. It has become, in consequence of the labours which M. Le Chatelier, M. Jacquernart, M. P. Morin, and I have undertaken to extract the alumina and prepare aluminium from it, a complete system of manufacturing industry. I may say that in the factory of Salyndres, where a manufactory of aluminium is now established, this process is daily employed to produce large quantities of aluminate of soda, soluble alumina, and aluminium.

I prepare a concentrated solution (4.5°) of pure caustic soda, which I introduce into a silver crucible. To this I add a weighed quantity of the aluminous mineral previously freed from chalk by digestion with weak

hydrochloric acid in washing, and I slowly evaporate it to the consistency of a thick syrup. It may, however, without inconvenience be evaporated to dryness. This may be useful in a quantitative experiment.

Upon adding water aluminate of water is dissolved, and a silico-aluminate of soda is left with oxide of iron, insoluble in water but soluble in acids. I will examine these two substances successively.

A. Silico-Aluminate of Soda and Oxide of Iron.—When the solid pulverulent matter, insoluble in water, is taken up by nitric acid, it almost entirely disappears, leaving a few grains of considerable hardness.

Corundum.—These grains, which resist the action of acids, dissolve in bisulphate of potash. They consist chiefly of alumina, with traces of iron and titanium. They are corundum.

Silica.—Upon evaporating to dryness the acid liquid and taking up the residue with water containing a little nitric acid, silica is left behind, which may be washed, ignited, and weighed. It soon disappears in weak hydrofluoric acid.

Titanium.—But this silica is not pure, for upon digesting it with sulphuric acid containing 50 per cent. of anhydrous acid, and evaporating until it begins to fume, a soluble substance is extracted from it which is separated by evaporating to dryness and ignition in a platinum crucible. This slightly yellow, flaky substance is then insoluble in the acid. Heated to redness with carbonate of potash, it is transformed into a brilliant saline body, the crystals of which separate from the fused mass at the moment of solidification. On treating the fused mass with water, a titanate of potash is left insoluble in water, but easily dissolved in hydrochloric acid. A portion of this solution treated with a slip of zinc yields a violet blue liquid, in which a dark blue precipitate soon forms, which is gradually whitened by the oxygen in the air. The hydrochloric solution treated by ammonia gives a white precipitate, which, when heated in the reducing flame with a globule of tin, produces a very dark violet blue colour, almost black. It is, therefore, titanous acid.

Soda.—The acid liquid, separated from the silica and titanium, is evaporated to dryness, and heated on a sandbath to about 200°, and then taken up by water, slightly ammoniacal. A nitrate is dissolved out, from which the ammonia is driven off by a gentle heat and the nitric acid by evaporation with excess of hydrochloric acid in a porcelain dish. The solution upon evaporation leaves well-defined cubes of chloride of sodium.

Iron.—The ammoniacal liquid leaves a considerable residue of a strong yellow colour, which dissolves entirely in hydrochloric acid. The iron may be easily separated from it by any well known process.

Alumina.—After the iron, the presence of alumina may be easily shown by methods which need not be detailed here.

Upon making a quantitative analysis by the above

process, and separating the iron and alumina by means of gaseous hydrochloric acid; I found the following results. The mineral was attacked by potash:—

	Oxygen.
Silica	41.9
Titanic acid	9.0
Alumina	25.6
Potash	23.5
	100.0

Excess, 1 per cent.

It is seen that this is the proportion of oxygen in Labrador feldspar. Only two or three equivalents of water must be added, which make it a sort of amorphous zeolite. The water is very difficult to estimate, for this body, like zeolite, loses water in a dry atmosphere and absorbs it again in a moist one, so that its normal composition is on this account very difficult to give accurately.

B. Substances Dissolved in the Soda.—When bauxite is treated with hot concentrated alkali, and when the insoluble matters which I have just mentioned are separated, the solution contains only alumina, which may be separated from the soda by any well known process.

C. Aluminate of Soda.—This solution has a constant composition when prepared with an excess of bauxite; but a definite compound can be obtained with greater certainty by attacking the aluminous mineral in excess with carbonate of soda at a high temperature, as is done every day at Salyndres, and by prolonging the operation until the calcined mixture no longer effervesces with acid. There is thus obtained a neutral solution, taking into consideration the saturating capacity of alumina, and the composition of which is given by the following analysis, which was performed on a specimen obtained with caustic soda and alumina in excess. This solution, treated with hydrochloric acid, evaporated to dryness, gave marine salt, which was weighed, and insoluble alumina, which was ignited and weighed. I found the following proportions of soda and alumina:—

Alumina	53.9	2 Al_2O_3	52.9
Soda	46.1	3 NaO	47.1
	100.0		100.0

which seem to be invariable in all the experiments since made on specimens prepared with carbonate of soda.

However, when the alumina-soda lyes are very concentrated, they deposit a very dense hydrate of alumina, from which the soda cannot be entirely removed by washing. The analysis quoted above was made with a liquid containing about $\frac{1}{4}$ th of its weight in alumina, and upon lyes marking 10° on the hydrometer. In all cases the aluminate $2 \text{Al}_2\text{O}_3, 3 \text{NaO}$ appears to be the most stable of all alkaline solutions saturated with alumina. The others may be considered as super-saturated when they deposit spontaneously.

Vanadium.—Some aluminate of soda which I kept for a long time in a well stoppered flask, deposited at the end of some months octohedral crystals of the greatest regularity, which might be taken for alum. These crystals, of which I had only very few, were at first looked upon as an aluminate of soda corresponding to M. Frémy's aluminate of potash, which also crystallises in the regular system, but they lose 48.7 per cent. of their weight by heat. Treated with hydrochloric acid, they disengage chlorine and become of a deep red colour.

This characteristic showed me for a certainty the presence of vanadium. Indeed, before the blowpipe they give with phosphorus salt, and in the reducing flame the beautiful green tint of vanadium, becoming yellow in the oxidising flame and orange yellow in the presence of nitre.

Finally, when dissolved in water and treated with sulphide of ammonium, they give the characteristic colour of alkaline sulpho-vanadates. These crystals, although they show in so marked a manner all the reactions of vanadium, do not really contain much; they are almost entirely composed of tribasic phosphate of soda, corresponding to the salt already known, and which, according to Mr. Graham, contains 56 per cent. of water and three equivalents of soda for one equivalent of ordinary phosphoric acid. According to this hypothesis, which I have not verified exactly, these crystals would be composed of,—

Neutral phosphate of soda	95.4
Neutral vanadate of soda	4.6
	100.0

The vanadic acid was estimated by dissolving the salt in a little water, placing a piece of sal-ammoniac in the solution, washing the precipitated vanadate of ammonia with sal-ammoniac dissolved in water, igniting and fusing the vanadic acid before weighing it.

The other elements of the salt were estimated in the following manner:—In the neutral solution from which the vanadate of ammonia has been separated a little ammoniacal nitrate of magnesia is poured. The precipitate of phosphate of magnesia and ammonia is filtered off at the end of some days, calcined and weighed. The liquid containing the nitrate and chloride of ammonium, with the nitrates of magnesia and soda, is poured into a flask and boiled down with an excess of nitric acid, which burns the ammonia and drives off the chlorine, so that there only remains soda, magnesia, and the excess of nitric acid. The latter is driven off by evaporating to dryness in a platinum dish. Re-dissolve in a small portion of water, and place in the liquid an excess of crystallised oxalic acid. Evaporate again. During this operation the greater part of the nitric acid is driven off by the oxalic acid. Moisten the residue with a concentrated solution of pure tartaric acid, containing only a few centigrammes of acid, dry and calcine, when there is obtained a mixture of magnesia and alkaline carbonates, which are separated by water. The alkalies are estimated in the ordinary manner.

This analysis, performed upon very small quantities of material, and by a method of estimating the phosphoric acid in which I have no great confidence, gave me evidently insufficient results. No simple formula can be deduced from it; it must only be regarded as an approximation. If I can procure a larger quantity of the crystals I will perform the analysis again. These are the results:—

Vanadic acid	4.4
Phosphoric acid	10.4
Soda	32.8
Potash	1.7
Water	48.7
Loss and fluorine?	2.0
	100.0

It may be remarked that, according to the observation, the phosphate of soda, 3NaOPO_3 , containing 56 per cent. of water, and which very probably enters into

the composition of this salt, is insoluble in a concentrated solution of caustic soda; so that all the phosphorus of the aluminous mineral is found in these crystals, of which the quantity is always very small. I had forgotten to say that their production may be hastened by pouring alcohol carefully on to the surface of the aluminate. Care must be taken not to mix the two liquids, as alumina containing soda will then be precipitated, which will interfere with the experiment.

2. Preparation of Vanadium.—The process which I have always adopted to extract vanadium from aluminous minerals consists in treating them with half their weight of concentrated soda lye, to which a little nitrate of soda has been added. After being uniformly mixed, the mass is dried, heated to redness in an earthen crucible, and then extracted with boiling water. The moderately-concentrated solution is then placed in a series of Woolfs bottles, through which a very rapid current of sulphuretted hydrogen is passed. A green coloration is soon developed, whilst the alumina precipitates, and then the liquid becomes of a rose violet, and finally the colour of very deep permanganate of potash. It only assumes this tint after a very prolonged current of sulphuretted hydrogen has been passed through the liquid, the excess of which passing through the first bottles begins to dissolve in the succeeding ones. Then filter and wash the alumina, which is absolutely pure (except perhaps a little phosphoric acid), very dense, and wanting the translucency which is usually possessed by gelatinous alumina as obtained by precipitation with ammonia from an acid liquid. It may be washed with great readiness. The washing water need only be collected so long as they are of a red colour. The sulpho-vanadate of soda has such a considerable tinctorial power that a few centigrammes of vanadium suffice to impart to a litre of water a deep claret colour when in the state of an alkaline sulpho-vanadate.

The red liquid is heated with hydrochloric acid until it is exactly saturated or at most very slightly acid. A brown precipitate mixed with sulphur is thus formed, which is allowed to settle at a gentle heat until the liquid is quite clear and free from sulphuretted hydrogen. The solution is then decanted and the sulphide is collected on a small, thin paper filter, and afterwards burned in an oxidising atmosphere to transform the sulphide of vanadium into fused vanadic acid. The quantity of vanadium which colours these sulphuretted liquids so strongly is really very small; for after the most delicate analyses and the most scrupulous search, I have only been able to find in aluminous minerals the following quantities:—

Researches on the Relations existing between Atomic Weights, by M. J. S. STAS, Member of the Royal Academy of Belgium.

(Continued from page 230.)

Synthesis of Nitrate of Silver.—In order to determine the proportional number of silver with respect to the nitrate of this metal, I have performed the synthesis of the nitrate of silver, as has been already done by MM. Turner, Penny, and Marignac.

I have performed these syntheses in Bohemian glass vessels, and in a platinum retort. For this purpose I have made use of all the arrangements mentioned when describing the synthesis of chloride of silver, to retain

during the solution of the metal the nitrate of silver mechanically carried off by the nitrous gas; except, indeed, in one single case, where I effected the solution, the evaporation, and the fusion in a platinum retort, when it was impossible for me to pass the gases through a liquid to deprive them of the mechanically suspended solution of silver. I made use of vessels of different materials in order to examine the action which the fused nitrate had upon the glass.

The silver being dissolved, which requires from twenty-four to forty-eight hours, according to the quantity of metal employed, I incline the globe and adapt the neck to a receiver, and proceed with the complete evaporation of the solution. To effect this, I raise the flask to a temperature approaching, but always below, the boiling point of the contained liquid; this takes from forty-eight to seventy-two hours. When evaporated, I raise the temperature of the nitrate to its fusing point, and keep it there until it is of a constant weight; this sometimes is very tedious. To hasten its drying, and especially to drive away the last traces of nitric acid which the salt retains, I pass into the vessel a current of air which has been first deprived of organic matter by passing through a Bohemian glass tube heated to redness, and containing oxidized copper, and afterwards dried by means of chloride of calcium. I was obliged to pass the current of air over a long column of red-hot oxide of copper before drying it, because I found that the air of my laboratory, or even the external air simply filtered through cotton and then dried, slowly, but continuously reduces nitrate of silver heated to its fusing point, and still more quickly when fused, with elimination of nitric acid.

When the weight of the nitrate of silver was perfectly constant, having made a note of it, I again increased the temperature to fuse the salt, and kept it in a state of fusion in a current of air deprived of organic matter and water, until its weight became absolutely constant. In many experiments I have kept nearly 500 grammes of nitrate in a fused state, from eight in the morning until ten at night, without in the least diminishing its weight.

In spite of the constancy of weight of the fused nitrate, I wished to assure myself that this salt lost nothing when it was fused a second time *in vacuo*. I have thus found that the fused salt does not possess any appreciable tension of vapour, for after having five times exhausted the air, and each time replaced it by pure air, the globe containing 472.416 grammes of nitrate lost nothing in weight.

As the fused nitrate is very slightly hygrometric, a property which the crystallised salt does not appear to possess, I adjusted to the globe during its cooling a tube containing chloride of calcium, or acid pumice-stone, to prevent the access of moisture; besides which, the globe was hermetically closed, except only during the weighing.

Then the cork which closed the neck of the flask, serving at the same time to close the globe, was replaced by another cork, which was slightly grooved, so as to allow the air in the flask to be of the same density as the external air.

The nitrate obtained in every experiment in which I made use of purified air was perfectly colourless in the fused state, and of a pearly white, with a radiating fracture in the solid state; it was always neutral to test paper.

Of the eight syntheses which I give below, four were performed in globes of Bohemian glass, two in retorts of the same glass furnished with a receiver fastened to the

retort, and with a bent tube likewise fastened to the receiver to retain the silver carried off. The last two, VII. and VIII., were executed in platinum.

In No. VII. the solution of the metal was itself effected in a platinum retort. In this experiment I was unable to pass the gases resulting from the solution of the silver in the nitric acid through a liquid to retain the metal carried off. This synthesis, therefore, is necessarily faulty. In the eighth experiment the silver was dissolved in a glass vessel, and the solution with the washing waters of the apparatus were evaporated in the platinum retort. The nitrate was there dried, fused, and kept in fusion for six hours. The two operations performed in platinum have enabled me to appreciate how marked is the action of the air of the laboratory on fused nitrate of silver. I have taken great pains to prevent its decomposition by organic matter.

The identity of the result obtained in Experiment VIII. with the result furnished in Experiments I., II., III., IV., V., and VI., shows that nitrate of silver can be fused in glass without either attacking or decomposing it. Moreover, I have always directly verified at each experiment made in glass, that the weight of the globe was identically the same after as it was before the synthesis: at the most, there might be noticed an increase

of weight of three or four milligrammes, due to the silicic acid deposited on the sides and derived from the silicium in the silver.

I have stated above that the nitrate simply dried at its fusing-point, still loses weight when it is actually fused. The average loss is a twelve thousand five hundredth of its weight.

Pure crystallised nitrate of silver, dried for six months under a bell-jar with concentrated sulphuric acid, lost in an experiment tried on a tolerably large scale a four-thousandth part of its weight upon fusion. This salt, which would be considered by all chemists as anhydrous, loses, therefore, three times as much water as the salt obtained by direct synthesis and dried at its fusing-point. It appears to me probable, however, that all the loss experienced by the crystallised salt upon fusion should not be attributed to the disengagement of water; it may be that the air condensed by the small crystalline plates has something to do with it.

Although I think that it is most rational to consider the fused nitrate as a definite compound, I give in the following table the weights of the salt in both cases; besides, whichever hypothesis is taken, the results agree within extraordinarily narrow limits, and present an ensemble which does not admit of two interpretations.

Synthesis of Sulphide of Silver.—Up to this time M. Dumas is the only person who has attempted to perform the synthesis of sulphide of silver.

To ascertain the relative proportions of its elements, he has directly sulphurised silver by means of pure silver, which was passed in excess in the state of vapour over the red-hot metal. The mean proportion which he obtained, was one which corroborated Prout's law. In following this method, I made two series of experiments, the first, comprising three syntheses, was effected by

leading an excess of pure sulphur, in the state of vapour, over the metal heated to dull redness in a Bohemian glass tube surrounded with magnesia to protect it from the action of the gas flame; in the second experiment I replaced the sulphur by pure and dry sulphuretted hydrogen. In each case I drove out the excess of sulphur by a current of pure dry carbonic acid.

As in a preliminary experiment I ascertained the formation sometimes of traces of sulphurous acid, sometimes of sulphuretted hydrogen, I suspected the presence of oxygen and hydrochloric acid in the carbonic acid which I prepared from hydrochloric acid and marble, passing it first through a hot solution of bicar-

¹ The result of the VII. th synthesis being inexact, for the reason mentioned in the text, I have not taken account of it in calculating the mean.

bonate of soda, and then through chloride of calcium tubes. I therefore took the precaution to pass the carbonic acid before drying it completely,—

1. Through a hot solution of bicarbonate of soda;
2. Over dry bicarbonate of soda, contained in two U-shaped tubes;
3. Through a glass tube, 90 centimètres long, heated to redness throughout, and filled in its first half with copper reduced by hydrogen, and in its second half with a mixture of oxide of copper and of copper reduced by hydrogen.

The apparatus for the disengagement of carbonic acid is terminated by two U-shaped tubes, filled with chloride of calcium, and followed by two others containing pumice stone moistened with sulphuric acid.

The suspected causes of error were found to be real; indeed, although I took the precaution to allow the carbonic acid to disengage for three hours before heating the tube containing copper and oxide of copper, I found unequivocal traces of oxidation of the metal for a length of 5 or 6 centimètres when I heated the tube to dull redness; and, moreover, I found a very appreciable quantity of subchloride of copper formed, an evident proof that the current of gas carried over with it traces of oxygen and hydrochloric acid. As I only made use of a slow current of carbonic acid, I hope that I completely eliminated the above-named causes of error; but if I had to recommence these syntheses I should replace the carbonic acid by nitrogen, which is so easily obtained pure by means of air and red hot hydrogen-reduced copper.

The silver employed in my experiment was rolled between two plates of pure silver. The sulphide of silver produced was beautifully crystallised. To be quite certain of the result, I weighed the sulphide of silver twice: the first time, after having heated it to very dull redness in a current of carbonic acid, and the second time after having heated it in the same current sufficiently high to soften the glass and fuse a portion of the sulphide of silver.

In each case the weight of the sulphide was identically the same, the weighings of the sulphide having been performed in the five experiments three times in air and twice *in vacuo*. The results agree so perfectly that it is scarcely possible to imagine a greater precision in experiments. Thus, in spite of the prejudice which I conceived against my first syntheses on account of their disagreeing with those of M. Dumas, I now have not the least doubt of the accuracy of these determinations.

These are the results of the five experiments:—

(To be continued.)

Notes on Nitrification, by R. HAINES, M.B., Professor of Materia Medica, Grant Medical College, Bombay.

As I have already touched upon the question of nitrification, it may not be out of place to indicate the extent to which our knowledge of this process has been advanced by the most recent researches.

Nitric acid, it is well known, exists in the atmosphere, and is brought down with rain as nitrate of ammonia, together with an excess of ammonia in the form of carbonate. From the fact that Cavendish and others obtained nitric acid by passing electric sparks through moist air, the opinion has been hastily adopted, and diffused by means of the ordinary elementary works on Chemistry, that electric discharges in the air are influential, if not principal, causes of the production of this compound.

The exact and elaborate researches of our countrymen, Lawes, Gilbert, and Way, have demonstrated the fallacy of this notion. Large quantities of rain collected in the country during every month of three years, over which the experiments extended, the rain of thunder-storms, the condensed water of fogs and mists, snow and hail, were separately examined by new and refined methods of analysis. The final result may be given in Mr. Way's own words:—

"It appears to me that all we can legitimately prove from these results is, that neither in the case of nitric acid nor ammonia is the quantity present in the air sensibly increased by such influences as electricity, heat, &c.; for, so far as the water of rain is concerned, these compounds of nitrogen are evidently inversely proportionate to the quantity of water falling. In the case of thunder-rain, the fall being slight, we have a large proportion of nitric acid, although, even then, not much greater than is found in the water of fogs and mists when the influence of heat and electricity is not supposed. Where, however, a fair quantity of rain falls, accompanied with thunder, we find only the average proportion of nitric acid."

On the other hand, that nitric acid is produced naturally by the oxidation of ammonia, without the aid of other nitrogenous matter, was proved many years ago by the French Academicians, who, by hanging up a basket of purified chalk, saturated with carbonate of potassa, for a few months, over a vessel containing putrefying bullock's blood, obtained a large quantity of nitrate of potassa.¹ By raising the temperature, this change takes place with increased rapidity. Dumas has shown that by passing moist air mixed with ammonia over chalk moistened with a solution of potassa, at a temperature of 212° F., there is found, in the course of a few days, a considerable quantity of nitrate of potassa.² Here, again, chalk appears to be a necessary agent in the transformation; the importance of chalk in both natural and artificial nitre grounds has been already alluded to. M. Boussingault has been engaged in a very extended series of experiments on the proportion of nitrates contained in natural waters of all kinds, from lakes, rivers, springs, and wells, and also in every variety of soil.³ The results are most interesting, but I cannot do more than glance at the more prominent of them. As to the soils, few were altogether destitute of saltpetre. In the poor soil of dry and exposed forest land, the proportion is at its minimum; in a few cases no

Page 287 column 240

nitrate could be detected. In cultivated lands, especially those in which carbonate of lime was naturally contained, or to which it had been artificially added, the nitrates were in very large proportion; in the earth of hot-houses, strongly manured, and kept at a high temperature, it was at its maximum. Argillaceous marl, though uncultivated, always contained much. In the chalk quarries at Meudon, near Paris, the upper strata contained nitrates in considerable quantity; in the lower strata they were altogether absent. With regard to natural waters, their richness in nitrates was found to be intimately connected with the nature of the rock strata through or over which they had passed; in lakes surrounded by primitive (syenitic) rocks the merest traces of nitre were found; in waters flowing from the sandy and quartzose rocks of the Vosges, scarcely stronger traces; but in rivers that rise in or flow over calcareous soils, as the Seine, the proportion was very large, on an average equivalent to 15 parts of nitrate of potassa in a million of water, but varying from 6 to 62 parts in a million. His experiments also confirmed those of other observers as to the vastly-increased quantity of nitrates in the well water of large towns. In the water of a great number of wells in Paris there was never less than the equivalent of 206 parts of nitre in a million (= 1.80 grs. in one imperial pint), rising, in particular cases to so high as 1000, 1500, 2000, and in the highest 2165 in a million, equal to about 18.94 grains in an imperial pint,—nearly approaching the largest quantity found in the wells at Nassik. These estimations were performed by the direct method, or rather by two direct methods, which were always employed comparatively,—namely, the decoloration of indigo, and that of Pelouze, by a proto-salt of iron and permanganate of potassa. (In Mr. Way's experiments, the proportion of nitrates being exceedingly minute, the process was different; the water was evaporated to dryness, the residue re-dissolved, filtered, and re-dried for several times in succession, whereby all the soluble organic matter became insoluble; the pure salts were then heated in a combustion-tube with oxide of copper, and the nitrogen estimated by Dumas's direct method; from this the equivalent quantity of nitrate of potassa was obtained by calculation.) In most of the above cases, the occurrence of nitric acid is explicable, and in all probability, rightly accounted for in the way I have already stated: the ammonia present in the air is brought in contact with oxygen highly condensed, perhaps in a liquid state, in the interstices of porous substances, as chalk, and oxidised to nitric acid and water; thus, $\text{NH}_3 + 8\text{O} = 3\text{HO} + \text{NO}_3$ —the excess of ammonia yielding the base, whose affinity for the nitric acid predisposes to the union; the nitrate of ammonia so formed slowly decomposes with the chalk into nitrate of lime and carbonate of ammonia, which latter salt, having a basic reaction, determines, as before, the formation of nitric acid; and so on, *ad infinitum*. Such is the plausible theory of Kuhlmann; and no better can be found.

But this theory leaves unexplained the occurrence of nitric acid in the atmosphere; ammonia there is truly, but neither chalk nor any other porous or gas-condensing material.

The action of electric discharges has been shown to be productive of no appreciable effect whatever. All that appears thus far is, that ammonia must be pre-existent; all nitrogenous compounds (nitric acid included) can, by simple means, be converted into ammonia; therefore, nitrogen must already be in some previous state of combination, otherwise nitric acid will not be naturally

formed. It is necessary to say "naturally," because we can form ammonia, and, therefore, nitric acid, from pure nitrogen, by the use of proper materials, aided by a very high temperature, under conditions, that is, which do not occur in nature.

But a very great step in advance has now been made. Nitric acid has been obtained at ordinary temperatures without electricity, by the direct union of nitrogen with oxygen. On November 26, 1855, M. Cloëtz communicated to the Academy of Sciences of Paris a Memoir, containing the results of a series of experiments, of which the following is an abstract:—Atmospheric air, after having been perfectly purified from every trace both of ammoniacal and acid vapours, by passing through tubes containing alkaline carbonates and sulphuric acid, was slowly drawn through a series of flasks containing various substances of an alkaline nature, and more or less porous. The experiment lasted about four months, in the autumn and early in spring, the mean temperature being probably below the average of the year, or 51°F ., so that it was little favoured by a high temperature.

The first four flasks contained fragments of recently-calced brick; in the first, impregnated with solution of pure carbonate of potassa; in the second, with precipitated carbonate of lime; in the third, with precipitated carbonate of magnesia; in the fourth, with both precipitated carbonate of lime and carbonate of potassa. "The next four flasks contained, instead of brick, fragments of pumice, first calcined with sulphuric acid, afterwards washed with distilled water, then again heated to redness without the addition of acid. Each of these flasks contained, like the first four, and in the same order, alkaline or earthy carbonates, alone or mixed."

The ninth flask was filled with broken, porous bones, calcined at a white heat, and impregnated with a solution of pure carbonate of potassa. The tenth flask contained calcareous marl.

After now passing through a column of pumice impregnated with sulphuric acid, in order to remove any ammoniacal vapours which the air might have acquired from the last flask, the current passed successively into four flasks filled with uncalcined pumice, mixed with the same matters as had been added to the brick and calcined pumice of the first flasks.

The next four flasks contained,—the first chalk, slightly moistened; the second, calcareous marl, with alkaline carbonate; the third, an intimate mixture, in the form of bullets, of decanted kaolin and precipitated carbonate of lime; and the fourth, argillaceous earth, taken from one metre below the surface. Of these eighteen flasks, nitrates were found after the experiment in considerable quantity in all those containing the brick, calcined pumice, and ordinary pumice. In the chalk, the pure marl and the marl containing alkaline carbonate, and in the mixture of kaolin and carbonate of lime, traces only of nitrates were found; in the calcined bones, and in the argillaceous earth, none whatever.

This experiment conclusively shows that, without the presence of any acid or ammonia, pure oxygen and nitrogen may combine directly to form nitric acid by contact with porous substances, containing alkaline or earthy matters.

(To be continued.)

On a New Method for the Production of Chlorine, by M. LAURENS.

THE process proposed by M. Laurens for the preparation of chlorine consists in decomposing chloride of copper by heat. Here is a *résumé* of the operation:—First, prepare

by the following series, among others : we cite those not containing carbon :—

H_2SO_4	(wanting)
$H_2S_2O_4$	Dithionic acid
$H_2S_3O_6$	Trithionic acid
$H_2S_4O_{10}$	Tetrathionic acid
$H_2S_5O_{14}$	Pentathionic acid
HCl	Hydrochloric acid
HClO	Hypochlorous acid
HClO ₂	Chlorous acid
HClO ₃	Chloric acid
HClO ₄	Perchloric acid.

Professor Odling found that it is possible to pass from the first to the second member of this series by a process of direct oxidation.

NOTICES OF PATENTS.

486. *Distillation of Bituminous Substances.* J. YOUNG, Limefield, Edinburgh. Dated February 25, 1861.

THIS invention has reference to improvements in apparatus for distilling the Boghead minerals, bituminous coals, and other bituminous substances, and consists in the arrangement of a series of vessels constructed for this purpose, of stoneware, brick, or other suitable material, communicating with each other, and placed side by side, or in a circle, as may be most convenient. These vessels having been filled with the bituminous substance to be treated, are connected with a steam-boiler, and a jet of steam passed through the whole in succession, at a sufficiently high pressure and temperature for ensuring the proper distillation of the coal. The oils generated during the process are drawn off at intervals from the stoneware vessels, and when they have accumulated in sufficient amount and the charge in the first vessel is exhausted, this is disconnected and the jet of steam brought to bear directly on the second, while another newly charged with coal is made the last in the series. The process is, therefore, a continuous one, and the gaseous products of the distillation are allowed to pass off from that vessel which at the time happens to furnish the last outlet.

The improved arrangement of apparatus here described is calculated to facilitate the manufacture of mineral oils of the paraffin class, for which Mr. Young has long been celebrated.

488. *Oils.* C. CORROY-REGNAULT, Margaret Street, Cavendish Square, London. Dated February 25, 1861. (Not proceeded with.)

FOR the purification and refining of such oils as are usually manufactured by processes of distillation, the inventor treats the crude material with one of the following substances, employed in the state of powder,—viz., charcoal, brick-earth, clay, talc, steatite, chalk, slate, or coal-ashes. After being intimately incorporated with any of these, the impure oil or resinous substance is submitted to distillation, when the glutinous, gummy, or otherwise prejudicial matters are retained in the retort, and a partially-refined product passes over. It is proposed further to subject this to a second process of distillation from powdered quick lime, caustic soda, and generally small proportions also of chloride of lime, and one of the class of materials employed in the first process. A third treatment, similar in nature to the second, may sometimes be resorted to with advantage. The process is applicable likewise to the clarifying, decolorisation, and disinfection of oils and fats already manufactured.

The system of treatment here defined is undoubtedly capable of effecting great improvement in the quality of many crude oily products, as, for instance, those derived

from Irish peat and the inferior descriptions of mineral oil. It must be borne in mind, however, that processes involving the employment of large quantities of bulky, porous materials, and repetition of treatment, must necessitate great loss in the successive stages of the process of purification.

513. *Glue or Composition suitable for Covering the Caulking of Ships, &c.* W. J. HAY, Southsea, Hampshire. Dated February 28, 1861.

THE present is an improvement upon a former invention, for which letters patent were granted to Mr. Hay on February 1, 1858. The object now accomplished is the preparation of a material more elastic than heretofore, and devoid of the unpleasant odour usually attaching to these compositions. Instead of crude naphtha and rough creosote as solvents for the asphalt and caoutchouc, the inventor prefers to employ resin oil, and he makes the new composition of the following ingredients melted together :—The several varieties of natural bitumen or asphalt, vegetable pitch or tar, and resin oil are used with or without caoutchouc. The patentee claims, also, the employment of oil of turpentine, wood naphtha, or any spirit or essential oil.

The material here referred to is evidently a description of "marine glue," the manufacture of which, according to the original specification of Mr. Jeffery, must be seriously affected by the high price which shellac has commanded for some time past in the drug market.

514. *Improvements in the Treatment of Certain Ores containing Metals, and in Obtaining Products Therefrom.* R. LAING, Ince, near Wigan. Dated February 28, 1861.

THIS invention relates to the economical use and application of the gases which are allowed to escape from the leaden chambers in the ordinary process of manufacturing sulphuric acid. It is proposed to employ these waste gases for the purpose of rendering soluble the copper and other metals contained in the roasted pyrites left as a residual product after the extraction and conversion of its sulphur into sulphuric acid in the chambers. By washing with water, the soluble metallic compounds may then be recovered.

This proceeding is likely to meet with advantageous adoption in those vitriol works where iron pyrites is employed as the source of sulphur.

537. *An Ointment for the Cure of Sores.* C. STEVENS, Charing Cross, London. A communication. Dated March 2, 1861.

THIS ointment is composed of the following ingredients :—Litharge, one lb.; strong vinegar and olive oil, of each about a pint. These materials are first well incorporated, and then boiled till they form a thickish paste. It is recommended to apply the ointment by spreading on a surface of bibulous paper.

The patent remedy thus procured would be an intimate mixture of Goulard-water, glycerine, and common lead-plaster.

529. *Improvements in Distilling and Rectifying, and in Apparatus employed therein.* M. HENRY, Fleet Street, London. A communication. Dated March 1, 1861.

ACCORDING to this invention, the liquids to be distilled are fed continuously into a vessel or chamber in which they undergo distillation, and whence they run out as soon as they have parted with their volatile portions, the requisite degree of heat being obtained by an arrangement of steam pipes coiled within the still, and an outer steam jacket or casing. The inventor prefers the use of shallow vessels exposing large surfaces of liquid, by which the rapidity of distillation is promoted. A number of vessels contrived as above may be arranged at different

levels, and the liquid and steam caused to circulate from one to another, so that distillation may be carried on at various temperatures, and products of different degrees of volatility obtained. A thermometer is appended to each vessel in the series to indicate the temperature.

The arrangement of distilling apparatus here described is extremely ingenious. A further improvement would consist in passing the exit steam pipe through a supplementary tank or vessel wherein the liquid might be slightly warmed before actually entering the still.

554. *Glass.* T. PETITJEAN, Brydges Street, Covent Garden, London. Dated March 5, 1861.

AMONGST other claims for improvements of a mechanical nature in the apparatus employed for glass-blowing, the inventor enumerates the use of charcoal as a fuel especially adapted to these purposes, and, moreover, generally applicable to the manufacture of glass.

The bulky nature and quick-burning properties of ordinary wood charcoal are difficult to reconcile with the statement of advantages referred to in this specification.

CORRESPONDENCE.

Deodorisation of Sewage.

To the Editor of the CHEMICAL NEWS.

SIR,—I have read with great interest the information which from time to time you have given to your readers on the highly important subject of the deodorisation and utilisation of sewage. In a late number you report the successful application of carbolic acid as a disinfectant.

Up to the present time I believe that lime is the substance that has been most extensively used for the disinfection of sewage, but I presume it is found of little use except in very great excess.

I wish to inform you of a fact which has come repeatedly under my observation, which seems to prove to me that lime is not suitable for the disinfection of sewage. One part of my business has to do with the melting down of large quantities of animal fats, which is done by means of steam and sulphuric acid.

Necessarily there is a large quantity of refuse left behind when the fatty matter is separated. Now, to utilise this refuse and also to make it into a solid artificial manure by drying, I found it necessary to neutralise all the free SO_4H , which I did by adding a small quantity of lime. From the fat being melted with the least possible quantity of SO_4H there is very little free acid. Now, whenever the whole of the acid is neutralised and lime is in excess, then the mass begins to stink, and gas begins to come off. I should say that this occurs in about twenty-four hours, when the mass has been slightly heated by the steam-boiler flue passing round the iron pan or boiler in which it is placed.—I am, &c.

Manchester.

TECHNOLOGIST.

On the Estimation of Alcohol in Wine.

To the Editor of the CHEMICAL NEWS.

SIR,—In reference to a letter which appeared in the last Number of the CHEMICAL NEWS, I trust I have quite as keen a sense of honour and propriety as "Suum Cuique" in acknowledging the rights and privileges of others, and beg to assure that gentleman that he is greatly mistaken in supposing that I took the initiative for those experiments from another person, never having seen Mulder's work by Dr. Bence Jones, nor had I any recollection of the extract and discussion appearing two years ago in the CHEMICAL NEWS: therefore, if my experiments tally with Mulder's, it was the result of circumstances, and from close personal observation, that I derived that knowledge, having been requested by a wine-merchant, who complained of the discrepancies and irregularities of the Excise charges for duty, to institute a series of experiments, in order that he may be the better prepared in future to seek redress from the proper authorities—the same quality of wine being differently charged at two different ports. I commenced, of course, by distillation; and with the view of knowing how far to carry that process, so as to ensure

the entire elimination of the alcohol, I attached a graduated scale to the retort, and noted the precise moment when oiliness ceased to form in the tube as stated. Observing that it was just at half the bulk of the wine used, I had no difficulty in getting at the specific gravity and strength of the alcohol either as gain or loss, since, if the one was ascertained, the other, i. e. the extractive matter, was also known, and *vice versa*; and, to shorten the process, preference was given to its estimation as loss.—I am, &c.

JOHN HORLEY.

Nitrates in Water.

To the Editor of the CHEMICAL NEWS.

SIR,—I see that in your last Number you published the results of my analysis of a water from Tewkesbury, which contained a very extraordinary proportion of the nitrates of lime and potassa. I was so astonished at meeting with such a large quantity of those salts, particularly the latter, that I felt desirous of learning whether it was really a natural water. I learned that the well was situated on the site of a demolished inn, and was very near where the stables had formerly existed, that the water had been of fair quality for a long time, but all at once had changed its character; it is therefore most probable that some accidental waterfall had caused the oxidized products of the former stable to overflow into the well.

I am, &c.

WILLIAM HERAPATH, F.C.S., &c.,
Professor of Chemistry, Bristol, Old Park.

Bleaching Wood.

To the Editor of the CHEMICAL NEWS.

SIR,—I have some wood which, naturally nearly white, has, through neglect in drying, become brown and otherwise stained. The sap not having been evaporated, has filled the pores of the wood with coloured matter. I have tried various chemical agents to remove this colouring matter, but in vain, some of them make the matter worse.

Can any of your readers suggest any substance that may possibly bleach this wood so as to make it nearly white, or if not, tell me of any good work on bleaching which would be likely to give me the desired information?—I am, &c.

W. W. C.

Relations between the Elementary Equivalents.

To the Editor of the CHEMICAL NEWS.

SIR,—On comparing the equivalents of Cs, Rb and K, it will be found that they form one of those remarkable proportional triads of which K, Na and Li, I. Br and Cl. are familiar instances.

$$\frac{\text{eq. Cs} + \text{eq. K}}{2} = \text{eq. Rb nearly.}$$

$$\frac{128.4 + 39.3}{2} = 83.85.$$

It is an interesting fact that there should exist two of these proportional triads amongst five elements whose properties so much resemble one another.—I am, &c.

CHARLES W. QUIN.

Derivation of Names of Elements.

To the Editor of the CHEMICAL NEWS.

SIR,—I cannot trace the origin or meaning of the words "iron," "ferrum," or "zinc;" can any of your readers help me? Is "manganese" a mere transposition and repetition of the word "magnesia," with the compounds of which those of manganese were confounded till 1740? The signification of the rest of the names of the common elements seems tolerably evident.—I am, &c.

A TUTOR.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Constitution of the Acids of Phosphorus.—M. Lieben speculates (*Annales de Chimie et de Physique*, t. lxxiii., p. 92) that, setting pyro-phosphoric acid out of the question for the present, all the other acids of phosphorus may be considered as derivatives of a triatomic radical phosphoryle PΘ. Thus, he represents phosphorous acid as

and hypophosphorous acid as

These formulæ, he says, account for the fact that both of the above acids contain 3H, two of which in phosphorus and one in hypophosphorous acid are replaceable by metals. The theory of Berzelius, which represented the former as 3HO, PO₂, and the latter as 3HÖPO, did not satisfactorily explain this fact. In metaphosphoric acid, the author considers that the 2H which in hypophosphorous acid are combined with PΘ are replaced by Θ. Thus, the formula for metaphosphoric acid will be

M. Lieben believes that pyrophosphoric acid is tetrabasic, and thinks that until experiment has revealed more of the nature of this acid, it will be useless to propose a rational formula.

Another Chrome-Green.—Bichromate of potash heated with phosphate of ammonia forms, according to M. Guignet (*Bulletin de la Société Chimique de Paris*, No. 4, p. 76), an insoluble metaphosphate of chromium, which is not affected by a red-heat. A slight excess of the phosphate of ammonia must be employed. The same phosphate is obtained when the bichromate of potash is calcined with acid phosphate of lime. M. Guignet doubts its usefulness as a pigment, the colour not being sufficiently intense.

II. ORGANIC CHEMISTRY.

Synthetic Formation of a Saccharine Substance.

—M. Boutlerow found (*Bulletin de la Société*, No. v. p. 84) that when dioxymethylene is boiled with an excess of lime or baryta water the mixture, which at first is colourless, quickly becomes yellow, and soon passes to an intense brownish-yellow. The odour of dioxymethylene disappears at the same time, and a smell like that of burnt sugar is produced. No gas is evolved during the reaction. When the lime water is added slowly, the mixture being kept near the boiling point, and stopping when the colouration takes place, a neutral solution is obtained, in which carbonic acid causes no precipitate. Evaporated at first on a water bath, and finishing under an air-pump receiver, a thick, yellowish, syrupy substance is obtained mixed with some crystals. Treated with absolute alcohol, the uncrystallizable substance is removed, and a white crystalline powder is left. This the author found to be formate of lime. The alcoholic solution evaporated under the air-pump left an extract smelling like syrup prepared with burnt sugar, and tasting like liquorice juice, but acid to litmus. When heated on platinum foil it behaved like saccharine substances, but left a calcareous ash. It reduced the cupro-potassic tartrate even in the cold, and instantly when heated. Like the sugar of mannite, it had no rotatory power. The solution did not appear to ferment with yeast, but as the experiment was made with a very minute quantity of the substance, the author does not consider it decisive. Boutlerow made two analyses of the substance, but the results did not agree well. He considers, however, that in its composition the new substance approaches the bodies which mannite and some of its congeners furnish in losing one molecule of water, and

therefore he names it provisionally *methylenitane*. As the first example of the formation of a substance having many of the characteristics of a true sugar, by means of the more simple compounds of organic chemistry, the production of methylenitane, says the author, is a remarkable fact. Further researches will no doubt soon enlighten us more on the subject, so we leave for the present the author's speculations on the formation of the body, and the analogies with other reactions.

MISCELLANEOUS.

SCIENTIFIC NOMENCLATURE.

The following is extracted from a letter addressed by "C. W. M." to the *Athenæum*:—

Had Milton lived in our days, and studied the "ologies," I think it would have been to them, and not to the clannish names of the North, that he would have gone for illustrations in his Sonnet on the book called "Tetrachordon." Surely, that hard names are the curse of modern science, must be admitted alike by the ignorant and the learned.

Science is not for the idler. No man who has the industry and ambition to become a scholar will grudge reasonable pains bestowed on the language and classification of his subject. Much force, however, lies in the word "reasonable." In many branches of study, but especially in the sciences of observation, the demands made upon the student exceed, as I think, all reason. Mineralogy, organic chemistry, zoology, and physiology are all overdone with technical words, while botany (the ladies' science) is the very abyss of hard names. This might be tolerated if the names were final. But no systematic nomenclature, which is to conform to theory, ever can be final; for the theory itself must change with advancing knowledge. It seems to me that this common character of all theories has been much lost sight of by the inventors of names. Hence it is that to make ourselves acquainted with the results obtained by previous observers, we have to master in each science, not one set of names, but many systems. In botany, it would appear that no one thought he had done useful work unless he had added something to the already overwhelming mass.

In chemistry, the researches of previous years have led to the substitution of name for name, and symbol for symbol, one after another, so many deep that one does not know the "right" appellation of wood-naphtha, or how to ask for a liquid which used to be sold as "spirits of salts," and was *sometime* (as the epitaphs say) muriatic acid, hydrochloric acid, chlorhydric acid, and lately, according to a chemical reformer, hydra-chlora. Sulphates are called thionates by the organic chemists, who run up the Greek numerals until they get to *pentathionates*, and I certainly thought that the acme of descriptive nomenclature had been reached in "methylethylamylophenylammonium," until I found a recent author proposing to substitute for it a word three syllables longer by way of simplification: I forget exactly how he spelt it.

Is systematic nomenclature a necessity of systematic investigation? I think not. But as the consent of authorities seems to be, in practice, at least, against me, I can only venture to propound the question for discussion, and to state reasons for my own opinion. The present opportunity is a particularly favourable juncture for this discussion, because most of the sciences of observation show symptoms of a change in fundamental ideas.

The applications of mathematical physics to chemistry—of chemistry to the functions of animal and vegetable life—the use everywhere of improved optical methods, among which I may mention spectral analysis and examination by coloured or polarised light,—and, more than all the increasing tendency to view Nature as

one whole, and the increasing power to perceive universality in her laws—are threatening a complete and immediate disruption of all our existing theories.

And what is a theory? Our lexicon tells us it is a way of seeing—a mode of viewing. No mathematician, no accurate reasoner, ever thinks of a theory as being true, even potentially. It is a mode of viewing the truth, changeable with our point of view, and falling short of the truth by just so much as our limited reasoning falls short of the infinite variety and complexity of the universe, which we can no more grasp in its material than in its abstract form. The finite cannot comprehend the infinite.

These observations are trite; but it is just for the want of noting them that we are encumbered with the flood of names. These have been invented, and grouped, and changed, and re-grouped, and systematized, by each new theorist, as if his theory not only embraced the truth, but were the truth. Here and there some great man, like Linnæus, saw the real meaning of his doctrine, as a guide to generalization; and of his system, as an index to his facts. But he wrote only for the learned, and those who explained his system popularly inflicted his nomenclature on the student, but failed to render his idea.

It is a good thing for an objector to be able to point out a remedy. A good thing, I say, but not a necessary thing. A cook who has spoilt the dinner cannot expect his master to tell him how he should dress it; and an instructor, whose teaching is obviously bad, cannot expect a student to show him his business. Improvements can only be carried out by those who are thoroughly conversant with the details. An outsider can only indicate general principles, and give general advice. I shall content myself with suggesting the following negative rules:—Never invent a name for a thing which already possesses an exclusive one. Never alter an individual name to accord with any theory. Even if a name be not exclusive, do not distinguish, until absolute necessity arise. Look upon individual names as subjects for certainty and fixity; but upon systems as provisional modes of grouping them. Never treat as fact what is merely the consequence of a theory.

I do but ask of the botanists and chemists to follow an example already set them by mathematicians on the one hand, and by men of business on the other. What is an old treatise on botany or chemistry worth now? But the old mathematicians are still profitably read by rising men—indeed, a man can do but little unless he does read them. One has certainly heard of libraries so neatly packed that, like a new plant in a botanical genus, a new book revolutionized the whole arrangement.

Soapstone of Mylos, an important article of commerce in Turkey and Russia, where it is used as soap, has been analysed by M. Landerer, the result being—silice, 63; alumina, 23; water, 12; and sesquioxide of iron, 1.25. This mineral is of a greyish colour, and has schistose fracture. It can be cut into shavings, and adheres a little to the tongue; softens in water, dissolving gradually in it; and afterwards becomes white and greasy to the touch. It becomes grey again after desiccation.

ANSWERS TO CORRESPONDENTS.

H. Mulcaster.—The second lecture is not yet delivered. Indeed, we do not think it was intended to give more than one.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Analysis of Feldspar, Kaolin, and Clay,
by M. H. SAINTE-CLAIRE DEVILLE.

1. **Treatment with Soda.**—The experiments which I have already performed on this subject suggested to me the idea of attacking the powder of Orthosen feldspar, clay, and kaolin by a concentrated lye of caustic soda the prolonged digestion effects a kind of solution of these substances in the form of a thick turbid syrup. When this is poured into water, there is produced a true decomposition, similar to that of bismuth salts. The syrupy matter, may, in fact, be looked upon as a hydrated and strongly alkaline aluminous glass, which is split up into two parts by the action of water: the soluble portion is a silicate of soda without a trace of alumina; the insoluble part is a double silicate of alumina and soda of a constant composition, which gave me the following results upon analysis:—

Silica	44.6	6
Alumina	26.4	3
Lime	0.4	
Soda	14.9	1
Potash	1.0	
Water, by difference	12.7	3
	100.0	

The water is rather low, and its proportion only corresponds to 2.3, instead of to 3; but the reason is that these substances cannot dry in the air without losing their combined water in the manner of zeolites.

It is remarkable that the same result is always obtained when we treat by digestion in soda either a silico aluminous material with an excess of alumina as bauxite, or a substance with an excess of silica as feldspar. In the first case there is dissolved an aluminate of soda without a trace of silica; in the second case there is dissolved a silicate of soda with a trace of alumina, the residue being the same in both cases. The same product is obtained, perhaps with more certainty, by evaporating the concentrated alkaline solution to dryness, and slightly calcining the residue. In any case a tolerably large excess of alkali must be employed. The silicate insoluble in water is, it must be understood, soluble in acids. Clays and kaolin behave in the same manner when treated with the caustic lye.

2. **Treatment with Hydrofluosilicic Acid.**—The solvent power which hydrofluosilicic acid $[2\text{Si Fl}_3, 3\text{H Fl}]$ has upon alumina is considerable, and exerts itself instantaneously. I did hope that I should be enabled by its means to remove from clay all the

alumina, and investigate the condition of the residuary silica in respect to its solubility in weak alkalies, which would be of interest in relation to the constitution of the clay contained in hydraulic lime nodules.

It is seen, indeed, from the above observations, that the alumina prevents the solution of nearly double its weight of silica (in the proportion of $\frac{44.6}{26.4}$) when the mixture of the two substances in the hydrated state is placed in contact with an alkali which would dissolve each of them separately. But an unexpected reaction takes place when weak hydrofluosilicic acid, such as is always used, is placed in contact with ignited alumina. There is at first formed a neutral fluosilicate of alumina $—2\text{Si Fl}_3, \text{Al}_2 \text{ Fl}_3$. Then, when an excess of alumina is added, and the digestion prolonged, the fluoride of silicium is decomposed, silica is deposited, and there is formed hydrated and soluble fluoride of aluminium: $\text{Si Fl}_3 + \text{Al}_2 \text{ O}_3 = \text{Si O}_2 + \text{Al}_2 \text{ Fl}_3$.

The presence of fluosilicate of alumina is shown by filtering the acid liquid which has stood over the alumina (I have always employed alumina obtained from the ignition of ammonia-alum), and by pouring into it chloride of sodium, the almost insoluble fluosilicate of soda is precipitated, and hydrochlorate of alumina is formed, whence the alumina can be precipitated by ammonia. Upon washing and re-dissolving this, no residue of silica will be perceived when the hydrofluosilicic acid and the alumina have been mixed in the proper proportions. The same reaction takes place between kaolin and hydrofluosilicic acid. It is, therefore, perfectly useless to employ pure alumina for the experiments which I have just described: kaolin answers the purpose quite as well, and, when it is free from iron, products of great purity are obtained. However, as kaolins always contain a little feldspar, and as this is readily attacked by hydrofluosilicic acid, a little potash gets into solution.

Warm hydrofluosilicic acid has a slight acid odour which immediately disappears when kaolin in excess is added to it; the saturation is complete when the odour of clay, which is somewhat alkaline, is apparent in the liquid. There then remains no more hydrofluosilicic acid in solution, but only hydrofluat of alumina, or hydrated fluoride of aluminium.

But before this transformation takes place, and when the liquid is still strongly acid, if strong alcohol be added to it an oily matter precipitates, which soon solidifies by crystallisation, and which is a kind of hydrofluoaluminic acid. It is composed of

		Calculated.
Fluoride of aluminium	65.4	$3\text{Al}_2 \text{ Fl}_3$ 66.2
Hydrofluoric acid	10.5	2H Fl 10.4
Water	24.1	10HO 23.4
	100.0	100.0

If the acid liquid is evaporated, instead of being treated with alcohol, acid is evolved, and a crystalline substance remains, which, after being washed in boiling water and dried in the air has the following composition:

¹ *Annales de Chim. et de Phys.*, lxi. p. 326.

² It would be better to employ the formula of M. de Marignac, $\text{Si Fl}_2, \text{H Fl}$; but as chemists are not yet accustomed to it I will continue provisionally to make use of the old formula, which, however, should be abandoned, as the new one is simpler and more rational.

			Calculated.
Fluoride of aluminium	. 59.0	$2\text{Al}_2\text{F}_6$	60.8
Hydrofluoric acid	. 8.8	Fl H	7.1
Water	. 32.2	10HO	32.1
	100.0		100.0

The slight difference which exists between the calculated hydrofluoric acid and that found by experiment is manifestly due to this product being contaminated with the preceding compound, which is a little richer in hydrofluoric acid.

Finally, if dilute hydrofluosilicic acid is completely saturated with excess of alumina or kaolin, a liquid is obtained which, during evaporation, does not liberate acid, and has a faint alkaline odour; it deposits in proportion to the degree of concentration a crystalline powder, which, when dried by artificial heat, loses a little water, and possesses the following composition:—

			Calculated.
Fluoride of aluminium	. 59.7	Al_2F_3	57.3
Water	. 40.3	7HO	42.7
	100.0		100.0

It is a hydrate, the composition of which, varying slightly with the degree of desiccation, should be represented by the formula $\text{Al}_2\text{F}_3 \cdot 7\text{HO}$, having regard to the ease with which it loses water upon the slightest application of heat.

All these compounds are free from silica, and resolve themselves at a red heat into fluoride of aluminium, which can be volatilised in a platinum crucible at a red white heat. This operation, which cannot be effected without the intervention of atmospheric oxygen, is never quite complete, in that there is always obtained in the platinum crucible a slight residue of alumina often crystalline.

It is remarkable that fluoride of aluminium, so insoluble in water, so perfectly unattackable by acids, presents itself under these circumstances in the form of a hydrate dissolved in a perfectly neutral liquid. We may imagine, to explain this fact, that there is a hydrofluo-aluminic acid of the composition $\text{Al}_2\text{F}_3 \cdot 3\text{HFl}$, analogous, consequently, to hydrofluosilicic acid, and of which cryolite, $\text{Al}_2\text{F}_3 \cdot 3\text{NaFl}$, would be a neutral salt, as well as the potash cryolite $\text{Al}_2\text{F}_3 \cdot 3\text{KFl}$, which may be prepared by pouring into a potash salt a solution of alumina in hydrofluoric acid.

In this case the soluble fluoride of aluminium would be simply a neutral fluoaluminate of alumina (making use of the old nomenclature used for the fluosilicates), $\text{Al}_2\text{F}_3 \cdot \text{Al}_2\text{F}_3$, or the hydrofluo-aluminic acid, $\text{Al}_2\text{F}_3 \cdot 3\text{HFl}$, in which each equivalent of hydrogen is replaced according to the ordinary law for the formation of neutral alumina salts, by $\frac{3}{2}$ equivalent of aluminium.

As to the hydrofluo-aluminic acid, it may be prepared by dividing a certain quantity of hydrofluoric acid into two equal portions, saturating one of them with alumina and mixing.

The preceding analyses have been performed in the following manner:—Place the weighed substance in a weighed platinum-boat, and introduce this into a small tube of green glass, drawn out at one end and closed at the other with a cork, through which a glass tube passes. Pass through it a current of dry hydrogen and heat the boat and the tube to a temperature of 400° or 500° C. with a spirit or gas flame. Water and hydrofluoric acid are evolved, which strongly attack the glass. Upon weighing the boat after the operation, the loss gives the water and hydrofluoric acid, the weight of the residue

giving the fluoride of aluminium. This should be almost entirely volatile at a white heat.

In the same boat weigh a fresh quantity of substance which is mixed with seven or eight times its weight of pure litharge fused and powdered. Weigh the whole and replace the boat in the glass tube, through which a current of dry nitrogen must be passed (for the apparatus to produce nitrogen in analyses, see *Annales de Chimie et de Physique*, third series, vol. xxxv., p. 442); heat the mixture without fusing the litharge, and water only is evolved. The glass tube, if new, should not be attacked. Weigh after the operation. The loss of weight gives the water of crystallisation in addition to the water formed at the expense of the oxide of lead, which is transformed into fluoride, and of the hydrofluoric acid, the fluorine of which combines with the lead. With these two estimations of loss, and by means of two equations of the first degree, the composition of the substance analysed can be obtained. Let a be the loss in hydrogen, b the loss in nitrogen, and in contact with the oxide of lead we have,—

$$\begin{aligned} x + y &= a \\ \frac{9x}{20} + y &= b \end{aligned}$$

in which x represents the hydrofluoric acid, and y the water. It is evident that the quantities of hydrofluoric acid will be proportional to $a - b$, and that when $a = b$ it is nothing. This happens whenever the neutral fluoride of aluminium is analysed.

I have obtained in these analyses very fine specimens of fluoride of aluminium. It is, indeed, the most economical and quickest method of obtaining this beautiful substance.

It may also be prepared very easily in the amorphous state by fusing a mixture of equal equivalents of cryolite and dry sulphate of alumina. In this manner are obtained sulphate of soda and fluoride of aluminium, which may be separated by water. The fluoride is then distilled in a tube of gas carbon in a current of hydrogen. In this way Captain Caron and I have procured the fluoride of aluminium, with which we have reproduced in the dry way some artificial minerals. M. Damour and I have likewise obtained it by heating wavellite to red-whiteness.

I have, in particular, succeeded in obtaining it in transparent crystals, which have enabled me to observe their influence on polarised light. I was much surprised to see these crystals, which I took to be cubic, sensibly rotate the light between two Nicol's prisms. I re-measured the angles, and found that they were not right angles, but equal to 88.20° or 88.30° . This was rather difficult to determine exactly, on account of the weak lustre of the crystalline facets of fluorine compounds, and of this one in particular.

Fluoride of aluminium, therefore, crystallises in rhombohedra of about 88.30° , and not in cubes, as I hitherto supposed. (For the properties of this substance, see *Annales de Chimie et de Physique*, third series, vol. xlix., p. 79.) If it is wished to prepare cryolite artificially, the best plan is to treat non-ferruginous kaolin with hydrofluosilicic acid, which gives fluoride of aluminium. Upon causing marine salt to react upon the same acid slightly concentrated, and warm gaseous hydrochloric acid and fluosilicate of soda are obtained. In the cold there is obtained a solution of hydrochloric acid, and an almost insoluble precipitate of fluosilicate of soda. When this is calcined in a muffle, it is transformed into fluoride of sodium, which, when mixed and fused with the fluoride of aluminium, gives cryolite.

Cryolite may be also obtained by treating fluoride of sodium with hydrated fluoride of aluminium; it is precipitated in the pulverulent state.

The hydrofluosilicic acid I have prepared in all my experiments by passing steam, or better by allowing water to fall, drop by drop, on a coarse mixture of sand and pounded fluoride of calcium heated to redness in a tubulated stone retort, and condensing the vapours of hydrofluosilicic acid, which will be a sufficiently strong liquid to mark 17° of the hydrometer, and which may be brought by concentration up to 29° or 30° . Not a trace of silica is deposited in this operation. Hydrofluosilicic acid prepared by means of fluoride of silicon and water only marks 4° or 5° when the water has become solid with the gelatinous silica.

At 7° Baumé, hydrofluosilicic acid in solution contains 66 grammes per litre of anhydrous acid ($2\text{SiF}_6 \cdot 3\text{H}_2\text{O}$).

At 29° it contains 325 grammes per litre, and possesses its maximum concentration.

I have performed these determinations by taking 10 cubic centimetres of the acid under trial, and treating it with an alcoholic solution of acetate of potash, and washing with alcohol the fluosilicate of potash, which appears gummy, but which is readily permeated by liquids. Dry the filter, and weigh the fluosilicate after having heated it. The fluosilicates of soda are crystalline and tolerably dense salts, which only appear gelatinous and transparent because their index of refraction is scarcely superior to that of water itself. Hydrofluosilicic acid at 29° is a very powerful acid, which drives off by the aid of heat almost all other acids, sulphuric excepted. It cannot be preserved in glass, but it neither attacks wood nor organic matters, and it may be preserved in small casks. It changes glass into fluosilicate of soda with great rapidity. I am persuaded that it will become of great industrial importance when its economic manufacture is understood.

3. Iron and Pyrites.—Clay can be used instead of kaolin to prepare pure aluminous products. But it must not be imagined that the iron contained in the clay can be removed from it by treatment with muriatic acid. That which is in a state of oxide is dissolved, but there remains iron in the form of pyrites. To completely purify clays, they must be digested with a solution of hypochlorous or hypochloric acid, which may be very easily prepared by a method given by MM. Calvert and Davies (by heating in a water-bath a mixture of equal parts of oxalic acid and chlorate of potash, and collecting the gas in water). This is the analytical process which I have for some years taught my pupils at the Ecole Normale to dissolve metallic sulphides, and to estimate the pyrites in clays and hydraulic limestone. The pyrite is transformed into sulphate of iron upon contact with the hypochlorous acid, which does not attack the sesquioxide and carbonate of iron.

Clays thus treated become white and at once suitable for the manufacture of pure aluminous products by the methods just described.

4. Vanadium.—Whilst conducting my researches on the mineral from Baux, M. Terrell informed me that M. Beauvallet thought that he had found small quantities of vanadium in clay from the neighbourhood of Paris. I mentioned in the following terms this interesting discovery, hitherto unpublished, in the memoir of my own experiments, presented to the Académie des Sciences of Paris:—"I have heard in connection with researches which are not my own that vanadium is likely to become

more common than could be imagined. If the experiments to which I allude are confirmed, they will impart a still greater interest to a body which is at present extremely rare, but with which the labours of Sefstrom, Berzelius, Wöhler, and H. Rose have made us thoroughly acquainted."

And, indeed, M. Beauvallet shortly after published his own researches. This young chemist has shown me some very finely-crystallised vanadate of ammonia, which he had obtained from the clays of Gentilly. M. Terrell has since confirmed them by extracting small quantities of vanadium from the refractory clays of Forges-les-Eaux. It, therefore, seems to be well established that the presence of vanadium may be discovered in all aluminous, and often in ferruginous, minerals. Captain Caron has found it in the emerald of Naxos, in a certain number of natural aluminates, and lastly, in a very abundant iron ore found in the department of Cher.

Researches on the Relations existing between Atomic Weights, by M. J. S. STAS, Member of the Royal Academy of Belgium.

(Continued from page 245.)

Determination of the Relation of the Atomic Weights of Silver and Chloride of Potassium, Chloride of Sodium, and Chloride of Ammonium.

—The determination of the relations between the atomic weights of these four bodies can be made with such exactness that if we can arrive at the conviction or the certainty that the bodies experimented upon are pure, the result obtained should be considered as almost absolutely exact. I have, therefore, in these determinations, an infallible means of submitting Prout's law to a decisive irrevocable proof. I have, therefore, taken all imaginable care to procure these chlorides pure. To ensure this, I have had recourse to physical and chemical forces to separate the bodies which may be combined or mixed in a more or less stable manner. In order to make the results control each other, I have repeated the determinations so great a number of times that I much doubt whether there exists in the annals of chemical science an example of a greater endeavour to arrive at the discovery of the truth. I have devoted a whole year to these experiments, which are apparently so simple.

Determination of the Relation which exists between the Atomic Weights of Silver and Chloride of Potassium.—I will detail, as briefly as possible, all the means which I have employed to procure the chloride of potassium. This account may appear tedious, but it seems to me quite indispensable; for I attach great importance to the determination of the relation existing between these two bodies.

1. Chloride of Potassium from Chlorate of Potash.—The purest chlorate of potash which can be obtained by means of repeated crystallisation always contains iron, manganese, silica, and sometimes alumina and copper. M. de Marignac has already proved the difficulty of separating iron from both chlorate and perchlorate. To effect the elimination of these impurities, I add to a filtered and boiling solution of chlorate, rendered alkaline by pure potash, a few drops of sulphide of potassium solution. After boiling for a quarter of an hour, I filter the boiling liquid and add to it, still keeping it in ebullition, a fresh quantity of sulphide of potassium. If, after the first addition of the alkaline sulphide, the liquid has been kept long enough in ebul-

lition, the subsequent addition does not occasion the least discoloration. When this is the case, I quickly cool the solution, so as to obtain the salt in the form of a crystalline powder. The magma is introduced into a displacement apparatus, the bottom of which is closed by a linen plug, and washed at first with alkaline and afterwards with acid water. This apparatus is connected, by means of a caoutchouc tube, with a reservoir which is in communication with an air-pump. A few strokes of the pump immediately remove the mother-liquor and the salt appears dry. I then moisten it with pure water, a few drops only at a time, constantly working the pump until the liquid which escapes below has no alkaline¹ reaction, and neither precipitates nor colours nitrate of silver. When the purification is effected in this manner, very little washing water is required. Two kilogrammes of commercial chlorate yielded at one operation from seven to eight hundred grammes of salt, perfectly free from iron, copper, and chlorine, but still retaining silica, and sometimes alumina. I then dissolve it three times in succession in pure water, taking the precaution each time to cool the solution rapidly and eliminate the mother-liquor in the displacement apparatus, with the assistance of the air-pump.

I then decompose the chlorate thus purified and dried in a platinum retort by a careful application of heat. Traces of chlorine are evolved and a chloride is produced which has not the least alkaline reaction. Upon employing chlorate obtained by means of crystallisation only, and which consequently retains at least manganese, iron, and silica, a decided disengagement of chlorine takes place and an alkaline chloride is produced. The purest chloride, when it is decomposed without a judicious management of the heat produces, however, a very notable disengagement of chlorine.

Since the chloride thus procured still contains traces of silica, and sometimes of alumina, it must be purified from them. The following are the various methods to which I have had recourse to obtain this result:—

I fuse the chloride in a platinum crucible enclosed in a second crucible. I then introduce into the liquid a bent platinum wire, to the curve of which I attach a pellet of fine platinum wire. I thus collect together all the suspended matter. When there are no more brilliant points—for it is under this form that silica and alumina present themselves in fused chlorides—I allow the crucibles to cool slowly. When part of the chloride is solidified I decant it, and cause the portion still liquid to pass through the solid mass. I thus effect a veritable filtration of the fused chloride through crystals of the same substance.

The chloride, after it has been received into a platinum dish and become solidified, appears under the form of either a vitreous, colourless, and perfectly homogeneous substance, or as a crystalline mass, of a cubical structure, according as the cooling has been rapid or slow. In these two conditions it possesses a sensibly different specific gravity.

I have only made use of this chloride for my determinations when a portion dissolved in water produces a liquid which is neutral to test-paper and absolutely limpid, which is, I confess, very seldom.

The results given under numbers I. and II. (Second Series) were derived from two different specimens of chloride obtained in this manner.

The chloride thus purified was dissolved in pure water, contained in a platinum dish. After standing for

some time, the perfectly clear solution has been decanted into a platinum retort and mixed with chloride of ammonium, obtained by the direct combination of ammonia with hydrochloric acid, both pure and in the gaseous state. The mixture is evaporated to dryness. The residue, well dried, was introduced, by small portions at a time, into a platinum crucible, contained in a second one, and fused. After cooling, the still liquid portion of the chloride was filtered through the crystalline mass.

Chloride of potassium thus prepared has always been perfectly colourless and homogeneous. When dissolved in water it forms a solution absolutely limpid and perfectly neutral to test-paper.

Numbers III., IV., and IX., the weighings of which have been performed *in vacuo*, were effected with two different specimens of this chloride.

Although these chlorides have furnished such concordant results, they may, nevertheless, contain other chlorides. I have, therefore, attempted to satisfy myself on this point by two distinct methods,—firstly, by dividing one portion of these chlorides into four successive parts by crystallisation from a pure aqueous solution; and, secondly, by causing a chemical force to act upon the chloride,—that is to say, by uniting it into a perfectly definite compound susceptible of being well purified.

To this end I have saturated about 200 cubic centimetres of pure boiling water, contained in a platinum dish, with chloride of potassium, from determination No. IX. (Second Series), and I have rapidly effected its crystallisation. The mother-liquor, decanted and mixed with the washing waters, was evaporated until a pellicle was formed on its surface; this furnished a second mother-liquor, which was evaporated after the addition of the washing waters until a pellicle formed and yielded a third crop of chloride. The mother-liquor from this was evaporated to dryness. The four specimens of chloride which were obtained in decreasing quantities were mixed with a tenth part of their weight of pure chloride of ammonium and thus submitted to fusion.

All these chlorides were colourless and dissolved in water, producing a neutral and perfectly clear liquid. The results given under the numbers IX. a, IX. b, IX. c, IX. d, are obtained from determinations made with these four specimens of chloride.

3. Chloride of Potassium from Chloroplatinate of Potassium.—I have united chloride of potassium from the chlorate with bichloride of platinum, in order to separate the chlorides which it might contain, and which crystallisation would not remove. For this object I procured a sufficient quantity of pure platinum. To get this I followed the method described by Berzelius, which is, however, very expensive, inasmuch as it necessitates the complete destruction of a large platinum crucible in which the operation is performed. I have repeated the purification three times instead of twice, as recommended by the illustrious Swedish chemist. Platinum thus purified is much whiter than the metal met with in commerce, and when fused is excessively ductile and malleable, as M. H. St. Claire Deville has recently stated.

I then dissolved this platinum in weak aqua regia, employing for this purpose a Bohemian glass flask. The chloride, evaporated to dryness, was dissolved in alcohol. I then added an aqueous solution of chloride of potassium from the chlorate, taking care to leave the platinum in excess. The chloroplatinate of potassium was washed first with dilute alcohol, containing chloride of platinum in solution, and then with weak pure alcohol. The

¹ Acid?

chloroplatinate of potassium was mixed with a fourth of its weight of perfectly pure chloride of ammonium and calcined at a bright red heat in a platinum crucible. The residue was dissolved in cold, pure water, and the solution was filtered through pure, spongy platinum, which had been strongly heated and placed in a drawn-out funnel. I took the platinum sponge as a means of filtration because I found that a solution of alkaline chlorides passed through paper always took from it traces of silica.

In order to get rid of the small metallic particles which might have been carried through, I allowed the solution to remain undisturbed for at least twenty-four hours in a platinum dish. At the end of this time the liquid was carefully decanted, mixed with pure sal-ammoniac, and evaporated to dryness in a platinum dish; it was finally fused in a double platinum crucible. The fused chloride never presented any traces of brilliant spangles. It may be decanted to the last drop without any foreign body whatever being perceived. When solid it is perfectly colourless, and when dissolved in water produces an absolutely pure and neutral solution.

Numbers v. and vi. (Second Series) of the Table refer to chloride of potassium purified from chloroplatinate of potash; and Number vii. to the same chloride, which was twice combined and twice separated by the means just indicated.

3. Chloride of Potassium from Nitre.—Two different specimens of nitre, weighing about 250 grammes each, which had been crystallised at least ten times each, and were completely freed from iron, manganese, copper, &c., were mixed with one and a-half times their weight of pure chloride of ammonium. Each of these mixtures was projected, little by little, into a large platinum capsule heated to full redness. The first portion of the mixture attacked the platinum pretty strongly, but when once the bottom was covered with alkaline chloride the additions of the liquid could be continued without sensibly altering the metal. At each addition a deflagration was produced. The resulting chloride of potassium was pulverised and mixed with a tenth of its weight of pure sal-ammoniac and of chloroplatinate of ammonia. The whole was fused in a double crucible of platinum. The platinum derived from the decomposition of the chloroplatinate of ammonium carries down with it to the bottom of the crucible the silica which the purest nitre always contains. After standing a certain time, the liquid is decanted into a platinum vessel. The chloride of potassium thus obtained has a very decided violet tint, due to the presence of very finely-divided platinum.

To separate this platinum, I dissolve the chloride in cold, pure water, and filter the solution through strongly-ignited platinum sponge. The filtered liquid, after standing for twenty-four hours, was treated in the way described for chloride of potassium extracted from the chloroplatinate of potassium.

The two specimens of chloride thus produced were each perfectly colourless, neutral to test-paper, and yielded with cold water an absolutely limpid liquid.

The determinations of Numbers viii. and x. (Second Series) refer to these two specimens.

At least fifty grammes of the chloride of Number x. were dissolved in pure water and divided by crystallisation into four successively diminishing portions, as explained in the case of the chloride prepared from the chlorate. I have determined the proportional relation of the four specimens thus obtained; the result is given in Numbers x. a, x. b, x. c, x. d (Second Series).

4. Chloride of Potassium prepared from Tartar.—Cream of tartar, crystallised ten times, was carbonised in a silver crucible and the carbon exhausted with pure water. The carbonate of potash was mixed with an excess of pure hydrochloric acid and the liquid evaporated to dryness. The residue was heated to dull redness and taken up after cooling with cold water. The solution was allowed to rest until it had become perfectly limpid by the deposition of silica; then decanted and supersaturated with ammonia it allowed traces of peroxide of iron and alumina to be deposited. After the liquid had again become clear I evaporated it in a platinum vessel and mixed the residue with a tenth part of its weight of pure sal-ammoniac and of chloroplatinate of ammonium. The mixture was fused, and the resulting chloride, as I have explained in the case of the chloride of potassium, prepared from nitre.

This chloride was absolutely colourless, neutral, and dissolved in water, forming a perfectly limpid liquid.

The results given under Number xi. refer to the chloride prepared in this manner.

(To be continued.)

Notes on Nitrification, by R. HAINES, M.B., Professor of Materia Medica, Grant Medical College, Bombay.

(Continued from page 246.)

A further step has been taken by M. de Luca, who has shown that porous substances were not essential to this combination. Air was ozonised by passing over phosphorus, then purified by passing through carded cotton, and over potassa and sulphuric acid; the pure ozonised air then passed over potassium and pure potassa. In three months the potassium became converted to potassa and deliquesced, and from both alkaline solutions nitrate of potassa could then be separated by crystallisation.¹

Oxygen, then, in the form of ozone, required but the concomitant predisposing affinity of an alkali to unite at once with nitrogen as nitric acid. Ozone, as Schönbein has shown us, is produced whenever an electric spark traverses atmospheric air; hence, in Cavendish's experiments it is ozone which is the medium of the combination, the water of the air and the gas jar playing the part of base, and not a feeble one, to the newly-formed acid.

But ozone, besides being produced artificially during the slow combustion of phosphorus and by electric sparks, is a natural and normal constituent of atmospheric air: it is believed to be chiefly formed during the evolution of oxygen by the leaves of plants. It is comparatively abundant in the air of rural districts, but disappears almost completely in the air of large towns or in crowded dwelling-houses. It remained, then, with regard to the nitrifying powers of oxygen and uncombined nitrogen, merely to put to the crucial test of more natural conditions the phenomena thus artificially evoked.

This also has been effected by M. de Luca. He prepared three sets of apparatus similar to those last described, but without the ozonising portion, by which atmospheric air was slowly drawn first through carded cotton, then over sulphuric acid, then over potassium, and, lastly, over hydrate of potassa. Two such apparatus were set to work in the court of the laboratory of the College of France, and one in a hot-house of the Botanic Gardens at the Luxembourg. The apparatus worked only during the day for six months; at the end of that

¹ *Comptes-Rendus*, December 31, 1855.

time both the potassium and the hydrate of potassa had run down into liquid potassa in all. In this liquid, in the two apparatus in the open air at the College of France, not a trace of nitric acid could be found; in that in the hot-house there was abundance of nitric acid, so that nitrate of potassa had begun to crystallise out.

There are, therefore, two distinct methods in which nitric acid is formed in nature, which are alike only in this, that both are processes of oxidation, and that in both the presence of some powerful basic material is essential to determine the combination. In the one, ordinary oxygen and ammonia are, by the agency of porous bodies, condensed in their pores, and in the presence of alkaline bases made to combine and form nitrates of such bases; in the other ozonised oxygen, whose affinities are vastly more powerful, unites directly with nitrogen in the presence of strong bases. Both these processes, there is every probability, go on incessantly; the nitric acid of the air being chiefly formed by the latter method; that of the soil chiefly, but not exclusively, by the former; not exclusively, because if ozone can oxidise nitrogen without the intervention of porous bodies, still more readily will it do so when it meets with them along with ordinary oxygen.

The question, in reference to the researches of De Luca, is of interest in another way, as it concerns the balance of organic nature. Hitherto it seems to have been the received doctrine that the quantity of combined nitrogen in the globe was constant, not susceptible at least, of increase. Philosophers have, I know, been chary of broadly stating this in so many words, but it is tacitly assumed whenever the subject is touched upon in the works of Liebig, Dumas, and others of the organo-chemical school which they have established. It is concluded, without dispute, that the nitrogenous proximate principles of animal bodies are directly derived from the nitrogenous principles of the vegetables which form their food. Animals appear to be totally destitute of the power of assimilating nitrogen, as such; neither can they convert such simple compounds as ammonia or nitric acid into the complex principles of animal life. On the contrary, if the careful and concordant experiments of Regnault and Reiset, of Valentin and Brünner, and of Boussingault, are correct, a portion at least of such nitrogenous principles suffers entire destruction, and the nitrogen is evolved uncombined, for expired air always contains an excess of nitrogen, which can only be derived from the decomposition of nitrogenous compounds.

During the natural decay of animal structures the whole of the nitrogen is evolved in the form of ammonia, or of some of its modifications, and by this ammonia vegetables are nourished, and by further combinations the plastic materials which are to form the food of animals are built up. In this circulation of the nutrient materials of the animal and vegetable worlds, ammonia forms the zero point to which once in every round the nitrogen compounds unceasingly return,—not, however, as we have seen, without diminution.

Again, vegetables have as little power as animals to assimilate uncombined nitrogen, but their capacity to destroy such already-formed combinations far exceeds that of animals; the oxygen exhaled by the leaves is invariably mixed with pure nitrogen, which in some cases equals, or even exceeds, the oxygen in volume. This nitrogen can only be produced from the decomposition of the absorbed ammonia, or its equivalent nitric acid.

Moreover, the nitric acid which is formed so abundantly from ammonia is liable to total decomposition.

Whenever gunpowder or similar mixtures are burnt, the nitrogen of the nitrate is evolved in a free state, no longer capable of taking its place in the series of transformations. The cycle is to some extent a double one,—nitric acid forming the starting point of a loop line,—in every stage of which except one the combined nitrogen suffers diminution, thus:—

- | | | |
|------------|-----------------------|--------------------------|
| 1. Ammonia | { 2. Ammonia | 3. Vegetable* Principles |
| | 2. Nitric acid* | 3. Vegetable* Principles |
| | 4. Animal* Principles | 5. Ammonia. |
| | 4. Ammonia | |

The points of the series at which this diminution occurs are marked by an asterisk.

Of the original formation of ammonia we know little. The numerous experiments by which it has been attempted to show its production by the union of free nitrogen with nascent hydrogen, are all inconclusive. That it exists, however, in the interior of the earth, is shown by the fact of its almost constant occurrence in the vapours emitted from volcanoes, in the Solfonni of Tuscany (with boracic acid), and in solid masses of rock-salt. In Liebig's words, it "has not been produced by the animal organism: it existed before the creation of human beings; it is a part, a primary constituent, of the globe itself." But the amount given off in the atmosphere cannot be very great; hardly comparable, one would think, with the amount destroyed in the functions of animal and vegetable life. It is not, therefore, without some reason that the fears expressed in the following extract should have occurred to a thoughtful observer:—

"With regard to gunpowder, the question may well be raised, whether its use can be said to harmonise with the economy of Nature. I do not mean by this the consideration that men and animals are killed by means of firearms, but rather the fact that by the combustion of gunpowder a portion of nitrogen which formerly belonged to Nature's capital stock of ammonia, is turned off into the atmosphere as free nitrogen, no longer capable of taking a part in the molecular transformations of the vital organism. The result, therefore, cannot but be, that the capital stock of ammonia in Nature will, in course of time, be diminished; for we are unacquainted with any natural phenomenon whatever capable of augmenting it. If this be the case, the vegetable and animal kingdoms must, after some thousands of years, suffer diminution."

Our knowledge of the natural formation of nitric acid through the medium of ozonised oxygen, if worthy of interest on no other grounds, will at least satisfy our conceptions as to the universal harmony of natural operations, and will tend to relieve our fears for the well-being of a distant, and, we may now hope, flourishing posterity.

TECHNICAL CHEMISTRY.

The City Pumps,⁴ by H. LETHBRIDGE, M.B., M.A., Ph.D.,

⁴ From the "Quarterly Report on the Sanitary Condition of the City of London."

cases, show an enormous amount of saline and organic impurity. Up to the present time there have been thirty-four of the City pumps examined, and in every case the water has been fouled with surface drainage. Not one of them derives its supply from the deep strata of the London basin; and, excepting the pump in Glovers' Hall Court, and that in Guildhall Buildings, none of them furnish water that is fit for domestic purposes; indeed, it is difficult to understand what motive or inclination can lead persons to the continued use of them. If such water were supplied by the public companies of London, there would be an universal condemnation of it; for at the best of times, some of these pumps yield water which contains from 100 to 130 grains of saline and organic matter in the gallon; and all of them are excessively hard from the altered products of decomposition. The fact of the presence of ammonia, saltpetre, sulphate of lime, common salt, and organic matter in large proportions is sufficient to indicate the source of the supply; and the knowledge of the composition of the soil through which the water passes should warn us of the danger that may at any moment arise from its use. It may be that the water has often been drunk with apparent impunity, and that it has rarely shown any immediate manifestation of its morbid action; but it cannot be that the products of corruption can be constantly admitted into the human body without danger of insidious mischief,—and there is the still greater danger of the impurities of the soil passing unchanged into the water, and being a source of quick and certain injury. This is indicated by the circumstance that the water from the City wells is constantly changing,—that it is hardly the same from hour to hour; for the soil through which it passes is pierced in every direction with drains and sewers, and is charged with every species of corrupting refuse, which passes in variable proportions into the porous strata from which the water is pumped. This ought to tell us, not merely of the disgusting nature of the supply, but also of the dangers which accompany it. Experience has shown that wells like these are liable at any moment to receive the leakings from a cesspool or a sewer, and thus to be the immediate cause of fatal disease. In the autumn of 1854 there was a sudden and serious outbreak of cholera in the parish of St. James, Westminster. The course of the disease was confined to a small area in the neighbourhood of a favourite pump in Broad Street; and soon it was remarked, that of seventy-three persons who died during the first days of the visitation, sixty-one had been drinking the water of the pump. It was also remarked, that among persons who were living in the same street, and occasionally in the same houses, those only were attacked who drank the favourite water of the pump; in fact, in a number of cases which were particularly investigated, it was ascertained that persons who lived at a distance from the parish, and who had the water sent to them because of its supposed goodness, were seized with cholera and died. A full inquiry into all the circumstances of the matter proved that the well had become charged with cesspool drainage, and had thus acquired its poisonous action. The pollution had perhaps been going on for years, and yet the water had not betrayed it, and had been drunk with comparative impunity: indeed, its cool and sparkling qualities, the fatal fascinations of corruption, had gained for it such a high repute in the neighbourhood, that it was a favourite water, and was generally drunk. Another such a case occurred at West Ham, in Surrey, in the autumn of 1857. Suddenly at that place there was a visitation of

cholera in a row of sixteen cottages that were apparently isolated from epidemic influences. It showed itself along one side of the street, where, in a few days, thirteen persons were attacked with the disease, seven of whom died. Dr. Elliott, the Health Officer for the district, suspected from his inquiries that the common pump on that side of the street had been concerned in the mischief; its water was, therefore, examined, and it was found to be polluted with the soakage from an adjoining sewer. At once the use of it was interdicted, and, to make the matter certain, the handle of the pump was taken away, and from that moment the further spread of the disease was arrested.

Again: in the cholera visitations of 1848-9 and 1853-4, there were two striking examples of the influence of such water in the propagation of disease. The southern districts of London, comprising nearly a fifth of the population of the metropolis, were visited most severely with cholera at both of those outbreaks, and the persons who suffered most on each occasion, were those who drank the worst quality of water. The inhabitants of those districts are supplied by two rival companies, who obtained their water from the Thames at different parts of its course. In one case the water was charged with a larger amount of organic matter than in the other; and, although the conditions of the population were in every other respect the same, yet this had the effect of augmenting the mortality to a frightful extent. In the second visitation of the disease, the circumstances of the supply were changed: the water of the old company, which was once the worst, was then the best, and the severity of the disease was changed likewise; for those who partook of the still bad supply suffered as before, and their mortality was three and a-half times greater than their neighbours. Here was an experiment on a large scale, such as "no sceptical philosopher would have dared to propose," in which a large number of persons were placed under circumstances exactly alike, except in one particular, namely, in the use of a water charged to a comparatively small extent with organic pollution, and this determined the result—a mortality of 130 in the 10,000 instead of 37. A similar tale may be told of the cholera visitation of other places in this country. The town of Newcastle-upon-Tyne was supplied with comparatively pure water in the year 1849, and it then suffered but little from cholera; whereas, in the visitation of 1853, when there was so calamitous a loss of life from this disease, the water supply was made impure by the drainage from the sewers. "The same effect," says Dr. Farr, "was the result of the same cause in Hull, in 1849. And other examples may be cited, in which the converse happened, as at Exeter, where the inhabitants, after having suffered severely from cholera in 1852, obtained pure water, and escaped its ravages."

Nor are the percolations from the graveyards of a city less injurious; experience has demonstrated that this also is a prolific source of disease. Sir James Magregor relates, that when the British army was in Spain, about 20,000 soldiers were buried in a rather small space of ground; this was going on for two or three months, and soon the troops who drank the water from the wells of the neighbourhood, were attacked with dysentery and malignant fevers. The cause of the mischief was clearly traced to the hardly recognisable impurity in the water from the shallow wells. Here, however, in the churchyards of this City, there are the remains of ten times such a buried army undergoing decay; and in the whole of this metropolis, in a space of not more than 218 acres of soil, there were buried not long since as many as

50,000 dead in the year. In a generation of thirty years, this would give us a million and a-half of decomposing bodies in the surface soil of London; and through these the water percolates, to find its way into the porous stratum which supplies the shallow wells. At best, the change of this corruption is but imperfect, and the presence of ammonia and saltpetre tells of the process of decay, and indicates the danger which accompanies it.

All these considerations have forced upon us the conclusion that water from rivers and surface wells, contaminated with the refuse of drains, and the soakings from graveyards, is unfit for public use; and, with the knowledge of this fact, I should be wanting in my duty, as your sanitary officer, if I failed to inform you of it.

On Aniline Blue, by M. CH. LAUTH.¹

A COMPARISON of the formula of aniline violet, $C_{20}H_{17}N_3O_2$, with that of aniline red, $C_{20}H_{20}N_4O_4$, led me to think that by treating the latter with reducing agents, it might be transformed into the violet. I therefore tried all the ordinary reducing agents, but none produced a satisfactory result. When treating, however, a solution of aniline red in commercial alcohol with a salt of tin, I noticed that the colour of the mixture, which at first was yellow, slowly became brownish, then green, and finally blue. The red matter had disappeared, and a new product had formed—*aniline blue*. I soon convinced myself that the active agent in this transformation was aldehyde, commercial alcohol always containing a certain quantity of this body. I now prepared some chemically pure aldehyde by means of the aldehyde of ammonia. I also prepared pure mononitrated trianiline by the following process:—Rough aniline red was mixed with four times its weight of sand, and then treated several times with boiling water. The sand was used to retain the resinous matters which always accompany rough aniline. The aqueous solutions were now precipitated by means of common salt, and the precipitated colour was again treated as the rough product had been. This operation was repeated three times; the last solutions in boiling water were treated with a boiling solution of common salt, and on cooling the liquid deposited brilliant crystals of mononitrated trianiline.

These crystals are dissolved in sulphuric acid diluted with four times its volume of water, and to that solution the pure aldehyde is added. The reaction commences in a few minutes, and after a time, longer or shorter, according to the quantity of aldehyde and acid employed, the red colour completely disappears, and gives place to a beautiful blue. As soon as the change takes place, the liquid must be saturated with caustic soda, which causes an abundant precipitate of the new colouring matter. The liquor contains acetate of ammonia.

In the above reaction aldehyde may be replaced by most of the hydrides, the essential oil of bitter almonds, the hydride of valeryl, and the oils of rue and aniseed. Any acid or acid salt may also be substituted for sulphuric acid. It is most probable that the transformation of the red to a blue colour, is due to some reducing action. M. Willm, however, is occupied with the analysis of the products, and will shortly publish his results.

The new colour has the following properties:—It is soluble in alcohol, ether, glycerine, &c., and dissolves in acids and alkalis. It is precipitated from the latter solutions when they are saturated. It is completely pre-

cipitated from its solutions by tannin, which forms with it a compound totally insoluble in water, only slightly soluble in alcohol, but more so in acetic acid.

The blue compound possesses most of the chemical properties of the other coloured derivatives of aniline, but not their stability. At 200° it is completely destroyed. Light quickly acts on it. It dyes wool, silk, and albumenized cotton, and gives shades of colour of great purity. When combined with aniline red, it produces a violet incomparably more beautiful than the ordinary violet.

PROCEEDINGS OF SOCIETIES.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, October 29, 1861.

J. P. JOULE, LL.D., *President, in the Chair.*

Professor A. D. Bache, Superintendent of the United States Coast Survey, and Commander M. F. Maury, of the United States Navy, were elected Corresponding Members of the Society.

John Edward Morgan, Esq., M.B., was elected an Ordinary Member.

Mr. SPENCE brought before the meeting part of a mass of iron and copper pyrites containing abundance of large and well-defined crystals of pure arsenious acid.

Not only are these crystals a novelty as a natural product, but as an instance of rapid mineralisation they are interesting. The lump was found among a cargo of small disintegrated ore imported from Huelva, in Spain, and containing no solid masses of large size, and the lump was merely an aggregation of small pieces firmly agglutinated together and full of hollow cavities, studded over with the crystals of arsenious acid; and from the history of the cargo of ore it is not probable that more than twelve months has been required for their development. Heat does not seem to have been the cause of the metamorphosis, as there is no evidence of heat at all approaching to ignition having occurred; discoloration of the ore would at once have been the result of this.

The ore is chiefly a sulphide of iron and copper; but as an arsenide of one or both of these metals exist in it, decomposition of this latter must have taken place; the arsenic has become oxidised, and crystals of arsenious acid are the result.

The piece of ore will be deposited in the Society's mineral collection.

The discovery of these crystals being pure arsenious acid was made by Mr. Bottomley, Mr. Spence's assistant in his laboratory.

An interesting conversation followed, in which the fact was stated that arsenic is a constituent of nearly all the artificial manures which have superphosphate of lime as their basis; and in connection with this a report was named of arsenic having been found in some of the crops grown with such manures.

Professor Roscoe exhibited the beautiful lithographic map representing the dark lines in a portion of the solar spectrum, lately published by Professor Kirchhoff. The lines are printed in ink of six different shades, and are of six different degrees of thickness, so that the leading features of the spectrum can be at once recognised. The position of the bright lines produced by the incandescent vapour of certain metals is also given on the map, and the coincidence of many of these with the dark Fraunhofer's lines rendered evident.

Professor Roscoe stated that the length of the drawings when complete would amount to some twenty feet, and that to give an idea of the scale on which the map was

¹ *Bulletin de la Société Chimique de Paris*, No. iv. p. 78.

made, he might remark that the distance between the two double lines "D" is upwards of four millimètres. These maps are as yet only printed together with the memoir by Professor Kirchhoff, upon the Solar Spectrum and the Spectra of the Chemical Elements in the Transactions of the Berlin Academy; an English edition will, however, shortly be published, giving a translation of the original memoir, and containing the same drawings of the spectrum as those exhibited, which accompany the German text.

Dr. R. AUGUS SMITH read the first part of "An Examination into the Products of the Putrefaction of Blood." He found that 54° Fahr., or nearly so, was a marked temperature; that below it there was little putrefaction, but above it a large amount, which increased as the temperature increased as far as he tried, viz., to 72° F. The amount of gas given in twenty-four hours, from three quarts of diluted blood, was one hundred cubic centimètres, at 57° F. (16° Cels.), but on raising the temperature to 72° (22° Cels.) the amount of gas in the same period rose to 397 C.C., or four times the amount of putrefaction by fifteen degrees rise of temperature. When the temperature was below 54°, no gas could be collected for many days. A very short rise above 54° caused sufficient pressure to allow gas to be collected. These facts were used to illustrate climate and sudden spread of disease.

During the early period of putrefaction, the Author found the sulphuretted hydrogen and organic matter to increase rapidly. One hundred cubic centimètres destroyed 29 of a solution of permanganate; the amount then rose rapidly to 36, 40.6, 41, 60.2.

Nearly ninety-eight per cent. of the gas that escaped was found to be carbonic acid and gases with a similar action, i.e., absorbed readily by caustic alkalies.

The gases were found to be:—

Carbonic Acid.	Sulphuretted Hydrogen.	Residue.
82	—	17.32
85.78	—	14.22
89.72	—	10.28
95.40	—	4.60
96.20	—	3.80
96.07	1.58	2.35
96.43	2.78	0.79
97.62	0.06	2.31
97.09	1.93	1.98

The residual gas was found to consist of:—

Carbonic Oxide	4.8 per cent.
Carburetted Hydrogen	2.5 "
Hydrogen	6.2 "
Nitrogen	86.5 "

100.

Where the sulphuretted hydrogen is 1.5, the sulphur is to the carbon as 1 to 24.8

Both the oxygen and carbon of the carbonic acid are derived from the blood, which is therefore carried rapidly away.

The point of greatest importance was said, by the author, to be the separation of these substances, which do not seem to be pure gases, and which are entirely absorbed by alkalies, and partly by acids and metallic salts. The portion absorbed by acids salts was found to contain carbon and nitrogen, in the relation of 140 to 54, or as 100 to 38.5; but part of this was evidently as ammonia. In albumen it exists in the relation of 100 to 28.9. The whole of the putrefactive matters were not removed by acids or by acid salts. When the carbonic acid and sulphuretted hydrogen are removed, the putrefactive matters still remain. These gases, therefore, are not the only substances to be feared.

The condition in which these putrefactive bodies exist was then discussed. The author believed that one of the conditions in which solid substances were taken into the air was in solution, the solution itself being taken up as a

vesicle; and he instanced analogous cases, such as sulphuric acid and zinc when hydrogen is forming. The liquid evaporates and a concrete globule forms, leaving at last a portion of solid matter in various states. This condition can be supposed to occur readily in many cases, but it does not appear to be the probable result in all cases, as he cannot readily imagine vesicles coming through the close pores of bodies such as are penetrated by these vapours. Between the actually mechanical method of taking solid matter into the air, such as when waves are agitated by the wind, and the purely chemical method, such as when a liquid is transformed into a vapour by heat, there must be many intermediate stages. These stages are required, apparently, as we can scarcely imagine pure gases undergoing transformation similar to bodies in a putrefactive state; and we are not prepared with a theory by which diseases will be communicated without the agency of bodies in such a state of change—one of the oldest of theories and one promising to live long. Besides, the fact of a substance being found capable of being absorbed by metallic salts, and containing carbon with nitrogen in such a large amount, leads us to believe that bodies not very far removed from the substances decomposed are found in the vapours, and, if not far removed, capable of undergoing transformations so as to become farther removed, and by such transformations exercising their special influence.

MICROSCOPICAL SECTION.

October 21, 1861.

Professor WILLIAMSON in the Chair.

The following gentlemen were elected members of the Section:—Mr. Murray Gladstone, Mr. John Whalley, Mr. William Henry Heys, Dr. William Roberts, and Dr. Thomas Alcock.

The SECRETARY presented sixty specimens of soundings received since the last Session, from the commanders of various steamers and sailing vessels, amongst which were a number from the south coast of Ireland, banks of Newfoundland, coast of Nantucket, United States, north coast of Brazil, &c. The Secretary was requested to write a letter of thanks from the Section to each contributor.

The CHAIRMAN remarked that these specimens deserved the best attention of the Section, not only on account of their intrinsic interest, but to show the contributors that their kindness in preserving the soundings for the Section was fully appreciated.

Mr. DALE offered, with the assistance of the Secretary, to prepare the material, by separation from the tallow, &c., and Mr. Nevill, Mr. Heys, and several other gentlemen offered their assistance in mounting, examination, and reporting to the Section.

The CHAIRMAN observed that the method he employed in the preliminary examination of similar specimens, when freed from tallow and dried, was to stir the mass in a vessel of water, when most of the organic forms rose to the surface, in consequence of containing small quantities of air; the creamings off the top of the liquid would be found to contain sufficient indications whether the specimens deserved further attention.

The SECRETARY read a letter from Mr. Joseph Sidebotham, accompanying a specimen and a drawing of the Aulacodiscus formosus, showing the four projecting knobs or handles visible upon that diatom. Mr. Sidebotham states that in all drawings hitherto published, these protuberances appear like simple elevations or bosses, nor could they be seen otherwise until the binocular microscope revealed their true shape. Mr. Dancer first called his attention to this peculiarity.

Mr. CROMPTON exhibited, and presented to the members, specimens or capillary tubes used by him to collect and preserve fluids for microscopical examinations for medical purposes. Mr. Crompton has used such tubes for more

than a year, and has preserved specimens of blood, urine, &c., which by any other method would have spoiled. The main feature consists in hermetically sealing the tubes after the introduction of the fluid, by holding their ends alternately in the flame of a candle or lamp until the glass melts, and the orifice closes; the tubes may be about three-fourths filled by capillary attraction or immersion, and care must be taken not to allow the fluid to approach the hot end of the tube whilst being sealed. The Edinburgh vaccine tubes answer the purpose well; they may be about three inches long, and a number of them may be carried in a small pocket case at all times ready to be filled. When required for examination, the tube is broken, and the enclosed fluid placed under the microscope.

The SECRETARY exhibited a specimen of the compound salt of magnesia and copper, prepared by Mr. Thomas Davies, of Warrington. Doubts have been expressed if it were a true compound salt, or a mere mechanical mixture, Mr. Dale, who at the Secretary's request had prepared some of the salt, undertook to report further upon it. Some forms of crystal were exhibited, producing novel effects by polarised light.

Mr. LYNDEN exhibited a fine specimen of copper ore, with jasper, from Cornwall, the colour of which, when illuminated with the Lieberkühn, was very gorgeous.

Mr. LATHAM exhibited the ovary of a flea, and portions of the skin and teeth of the dogfish.

Mr. HEYS exhibited specimens, mounted specially for the Lieberkühn, of various seeds, hairs, and glands of plants; the tessellated spines on the *Symphytum asperillum*, or rough comfrey, and the ruby coloured oil glands of the *origanum onites*, glowing, like precious stones, with the reflected light from the above object, was very much admired. For certain classes of objects no illumination can compare with that of the Lieberkühn in the use of the binocular microscope, and side lights may be obtained, to some extent all around the object, by manipulation with the mirror.

ROYAL INSTITUTION OF GREAT BRITAIN.

General Monthly Meeting, Monday, November 4, 1861.

WILLIAM POLE, Esq., M.A., F.R.S., Treasurer and Vice-President, in the Chair.

The Rev. W. Wentworth H. A. Bowyer, M.A., was elected a Member of the Royal Institution. Alexander J. Ellis, Esq., was admitted a Member of the Royal Institution.

CHEMICAL SOCIETY.

Thursday, November 7, 1861.

Dr. A. W. HOFMANN, F.R.S., President, in the Chair.

MR. HARCOURT, of Oxford, read a paper *On the Action of Certain Gases on the Peroxides of Potassium and Sodium*, the method of preparing these bodies having already been published in the *CHEMICAL NEWS*. His original experiment was to act on potassium and sodium with air and oxygen gas, the metals having been previously filtered through linen, and cast in a glass tube. Under these circumstances sodium combined with two equivalents of oxygen and potassium with as many as four equivalents. The action of water on these oxides had been investigated. Some difficulties arose in conducting the experiments, on account of the powerful action of the oxides on the material of which the containing vessels were composed; glass, platinum, and silver being rapidly attacked at a high temperature, a compound of oxide of silver with oxide of the alkaline metal being produced when a silver vessel was employed; in the case of

tetroxide of potassium oxygen was evolved at the same time. These results were obtained by heating the peroxides in a silver boat, and passing over them a current of nitrogen gas, the boat being placed in a glass tube. The action of vapour of sulphur on the peroxides of these two metals was next investigated, when a rather unexpected result was obtained; instead of a sulphate being formed, as might have been anticipated, a sulphide was produced, together with sulphurous acid gas. By the action of iodine on the binoxide of sodium a substance containing sodium, oxygen, and iodine was produced, which was probably a mixture of iodide and iodate of the metal. Carbonic oxide passed over the binoxide of sodium gave rise to the formation of carbonate of soda; with tetroxide of potassium oxygen was evolved and carbonate formed. Carbonic acid also produced carbonate of the metal, oxygen being set free both from the peroxide of sodium and of potassium. With protoxide of nitrogen and binoxide of sodium a nitrite was formed, nitrogen being evolved; this gas, however, seemed to have no action on the tetroxide of potassium. The action of binoxide of nitrogen gave rise to the formation of nitrite of soda; but with the tetroxide of potassium red fumes were produced at the same time from the combination of the oxygen set free from the peroxide with the excess of binoxide of nitrogen; the apparatus was filled with nitrogen before commencing the experiment. The product in this case was a mixture of nitrite and nitrate of potash.

The PRESIDENT inquired whether the substances were heated in the last experiments?

Mr. HARCOURT replied that, although heat was employed in most cases, the experiments with the oxides of nitrogen were performed at the ordinary temperature.

The PRESIDENT then remarked on the difference between the deportment of the two metals, potassium and sodium, and asked whether there was any appearance of a binoxide of potassium being formed previously to the higher oxide?

Mr. HARCOURT concluded, from the colour of the compound at an intermediate stage, that a lower oxide was first formed: he endeavoured to verify this by determining the increase of weight, but could not obtain a constant result: he also thought there was a possibility of a tetroxide of sodium existing, but the temperature necessary for its production being higher than that required for the preparation of the potassium compound, the containing vessel was destroyed before this point of oxidation could be reached.

A Paper, by Mr. F. A. ABEL and Mr. F. FIELD, *On some of the Results of the Analysis of Commercial Copper*, was then read by Mr. ABEL. After referring to the importance of determining accurately the amounts of arsenic, antimony, bismuth, and lead present in different varieties of copper, he stated that the usual method recommended in books on analysis for the separation of arsenic and antimony from copper, namely, by digesting the mixed sulphides of the metals in sulphide of ammonium, was imperfect, for that as much as one per cent. of arsenic, and even twenty or thirty per cent. of tin, might be overlooked, on account of the power possessed by sulphide of copper of holding back the sulphides of these metals, and preventing them entering into solution, as had been pointed out by Mr. Bloxam; and that a better mode of proceeding was to add ammonia to the nitric acid solution of the copper, and then pass sulphuretted hydrogen into the liquid, for that in this case the sulphide of copper was precipitated, whilst the sulphides of arsenic and antimony were retained in solution by the sulphide of ammonium formed at the same time. The following process was recommended for the analysis of commercial copper:—Two hundred grains of the copper were to be dissolved in nitric acid and filtered from slag, &c., a small quantity of a solution of nitrate of lead, and excess of ammonia, and a little carbonate of ammonia

were then to be added, the liquid filtered, and the precipitate washed and digested in oxalic acid solution, filtered from oxalate of lead and of bismuth; a stream of sulphuretted hydrogen passed through the filtrate after the addition of excess of ammonia, and after filtration from a little sulphide of lead, a slight excess of hydrochloric acid added, and the whole to be warmed for a few hours. The presence or absence of antimony could be ascertained with certainty from the colour of the precipitate obtained. For the detection of bismuth and lead, another portion of two hundred grains was to be dissolved in nitric acid, and a little phosphate of soda and excess of ammonia to be added, and the precipitated phosphates of bismuth and lead collected, washed, and dissolved in dilute nitric acid, tartaric acid and excess of ammonia added, and sulphuretted hydrogen passed through the liquid, the precipitated sulphides collected and dissolved in nitric acid, and the solution digested with hydrated oxide of copper, when oxide of bismuth would be precipitated, the oxide of lead remaining in solution; the liquid having been filtered, chromate of potash was to be added to the filtrate when chromate of lead would be precipitated. Iron if present would be found with the bismuth, and could easily be separated. The accuracy of these processes was tested in the following manner:—A hundred grains of electrotype copper were dissolved and treated as directed, and no yellow precipitate was obtained from the ultimate solution on addition of hydrochloric acid. To another portion of a hundred grains one-tenth of a grain of arsenic was added, and this could be easily detected, and even one-hundredth of a grain of arsenic in a hundred grains of copper could be discovered by the process. Antimony in equally small quantities could be separated in the same manner. The process was also applicable for the examination of commercial hydrochloric acid for arsenic. The presence of very minute quantities of arsenic could also be discovered in copper by the magnesia test; the copper to be dissolved in nitric acid, excess of ammonia added and then sulphate of magnesia, and the whole allowed to stand. By this process two hundredths of a grain of arsenic in a hundred grains of copper were detected. The method recommended by Mr. Field, namely, to separate the main bulk of the copper from the solution of the sample in nitric acid by adding oxalic acid; and to examine the filtrate for the other metals, was also efficacious, although the plan before given was preferable. Mr. Abel then alluded to the method recommended by Dr. Odling for examining copper for small quantities of arsenic, which was to act on the finely-divided copper, with cold hydrochloric acid exposing the solution to the air, and after the solution of the copper, to distil the liquid, when chloride of arsenic would be found in the distillate if arsenic were present in the copper. Mr. Abel pointed out that if heat were applied before all the copper was dissolved, arseniatted hydrogen was evolved, but that mere traces of arsenic could be detected in copper by placing a piece of the metal in hydrochloric acid and adding a small quantity of sesquichloride of iron or chlorate of potash, and leaving it to stand for some time, when a grey coating would be formed on the surface of the copper if it contained arsenic; also that a very small quantity of bismuth might be detected by adding to the solution of bismuth a little lead-salt and then iodide of potassium, when, if bismuth be present, a brown or crimson-coloured precipitate would be obtained instead of the bright yellow iodide of lead; in this manner one twenty-five-hundred-thousandth of a grain of bismuth could be detected. To apply this test to a specimen of copper, nitrate of lead is added to the nitric acid solution of the metal, and then ammonia and carbonate of ammonia, the precipitate dissolved in acetic acid and iodide of potassium added. Mr. Abel then said that bismuth had been discovered in a great number of copper samples, and that arsenic and silver were almost always present, but that antimony was very rarely found,

and lead never, excepting in manufactured copper, such as copper bolt and sheet, and that in these cases it was intentionally added.

Dr. ODLING said that he had observed that hydrogen was evolved during the solution of copper in hydrochloric acid, and that he preferred the use of chlorate of potash, to avoid the delay of exposing the liquid to the air.

Mr. RILEY remarked that he had found phosphorus and antimony in copper.

The PRESIDENT inquired whether the amount of bismuth in the new bronze coinage had been determined.

Mr. ABEL replied that the quantity was very minute, and had not, therefore, been determined.

Mr. DE LA RUE alluded to some analyses of commercial copper which Dr. Hugo Muller had performed; it appeared that Dr. Muller had found both sulphur and gold.

Mr. ABEL said that he had succeeded in detecting gold occasionally.

The PRESIDENT stated that the Duc de Leuchtenberg had examined the refuse obtained from copper in the electrotype factories, and had found a great number of metallic impurities.

Dr. MULLER had also examined these residues, but did not find so many constituents; the residue contained a considerable quantity of nickel.

Mr. DE LA RUE remarked that in the electrotype process the bulk of the copper was separated in a very satisfactory manner from the impurities, so that the residue might be easily examined.

Mr. F. FIELD then read a short paper *On the Occurrence of Bismuth in Various Descriptions of Copper Ore obtained from Different Parts of the World*; a table of analyses of various samples was exhibited, from which it appeared that, as a general rule, bismuth was only found in the sulphuretted ores of copper.

Mr. NEWLANDS then exhibited a tabular arrangement of organic bodies including substances of every variety of composition, the advantage of which arrangement was that the relations between the composition of different substances was more easily discovered.

It was announced that at the next Meeting Dr. Benoe Jones would read a paper *On the Occurrence of Phosphate of Lime in the Human Urine*.

NOTICES OF BOOKS.

Report of the Committee on the Decay of the Stone of the New Palace at Westminster.

CONCLUDING NOTICE.

IN February of the present year, the St. Stephen's Porch of the Westminster Palace was placed under the experimental treatment of Mr. Charles Hibble, of Grafton Street, Fitzroy Square. The process employed by that gentleman was one which had received application to the private dwelling-house, No. 49, Bedford Square, early in the year 1854; and which, according to a certificate from the owner of the house had completely remedied the symptoms of decay at that time apparent in the Bath and Portland stones employed in its construction. The materials entering into the composition of Mr. Hibble's preparation are turpentine, linseed oil, Dorking lime ground, silicate of lead, and burnt coppers; the two last named being used as driers. It is preferred to apply two coats, the second containing rather more linseed oil. Another ingredient is alluded to by Mr. Hibble as having been employed upon St. Stephen's Porch; this consists of a final coating of silver sand sifted through a dredger.

The general character of the process is described and admitted to be not very different from that presented by an ordinary coating of paint. This consideration, taken together with the complex nature of the preservative

agent, has not tended towards the establishment of a very favourable opinion in regard to this process.

Another mode of applying linseed oil is communicated by Mr. P. C. Hardwick, Architect of the Bank of England. This consists in the employment of an oleaginous preparation made as follows:—Linseed oil, one gallon; soft soap, one pound to a pound and a-half; alum, half a pound; and litharge, quarter of a pound. The oil, soap, and alum, without the addition of any water, are all to be heated together in an iron pot; when melted, the litharge, wrapped in a canvas bag, is introduced, and the whole kept constantly stirred for a period of three hours over a slow fire. After cooling the mixture will have the consistency of thin paint, and may be preserved in air-tight tin canisters for a considerable time. There is a tendency, it is said, for the alum to subside to the bottom of the vessels on longer keeping; this deposit would, however, with a greater degree of probability, consist of the heavy sulphate of lead produced as the result of the action of litharge upon the sulphates in the alum.

The circumstance which induced Mr. Hardwick to advocate a trial of this composition in connexion with the Houses of Parliament, was the observation that very satisfactory results had followed the application of the same material, some twenty years since, by the foreman of works, to brick walls and buildings, including stone window-sills, on a farm in Sussex, which by this means were rendered far less absorbent of moisture, and had resisted, in a remarkable manner, the disintegrating effects of the atmosphere.

A process somewhat similar to the last is described by Mr. G. R. Burnell, O.E., a member of the Committee, as having been practised more than twenty years ago upon the dome of the Pantheon and other stone buildings in Paris. Three parts of olive oil are mixed with one of beeswax and a little litharge, generally in the proportion of about one-tenth by weight. These ingredients having been thoroughly incorporated, with the assistance of heat, are, while still hot, laid on to the surface of the stone, which should previously have been, if possible, both dried and warmed by the employment of fire-baskets or braziers. Such treatment necessarily facilitates the absorption of the oily fluid into the pores of the stone, which is thus rendered much more repellant of moisture. The instance of its application abroad, already cited, is reported to have been undoubtedly successful, so far as regards the protection of the stone; but it must be remembered that the introduction of the oxide of lead as an ingredient in this and the preceding compositions must always be attended with the disadvantages arising from the gradual darkening, by sulphuretted hydrogen in the air, of the stone surfaces so coated.

Of the processes upon which the Committee have taken evidence, the last remaining to be described is the mode of treatment patented by Mr. William Hutchinson, of St. John Street Road, for the induration of stone by immersing the blocks in melted coal-tar, pitch, or common resin, using the first or second of these substances accordingly as the colour is desired to be black or white. Some very satisfactory and interesting particulars are furnished in regard to the preparation of paving slabs, tomb-stones, window-sills, fonts, and other small architectural ornaments. These, although they may have been cut from very inferior stone, will, after their induration, have become completely impervious to water; the frost cannot affect them, and their external surfaces, originally soft, (as with the Tunbridge Wells stone, for instance,) may now have a high polish imparted to them.

In considering the applicability of such a process to stones in position, obstacles are presented which appear almost insurmountable. The high temperature required for the fusion of these substances, and the necessity for drying and even warming the stone before being brought into contact with the melted material, are difficulties which

render it imperative to introduce some modification into the working of the process before it can be deemed applicable to the treatment of the Houses of Parliament.

With the present notice we conclude our critical review of the several processes which have been submitted and received the consideration of the Decay of Stone Committee; and in the ten pages of our journal devoted to the discussion of these proposals it has been our object to institute comparisons in regard to their probable efficacy as determined by an examination of the scientific principle which lies at the basis of each invention. Many of these suggestions appear worthy of extended investigation, and we entirely concur in the recommendation conveyed in the report, to the effect that it would be desirable to proceed further to a practical trial of at least one process in each class, and thus endeavour to secure without delay the opportunity of watching closely the relative capabilities of the several methods proposed, that some really valuable information may at length be acquired as to the best means of guarding our great national edifice from the ultimate and more serious consequences of confirmed decay. An important condition of such competitive trial must consist in requiring each candidate to give an explanatory statement in reference to the materials themselves and the mode in which they are about to be employed; for not only would such a course furnish a guarantee that no permanent injury to the face of the building would be likely to result from the treatment proposed, but such data must always be available for the information of those who may hereafter be entrusted with the supervision of the experimental results, and when, at the expiration of a sufficiently long interval of time, the comparative efficacy of these applications shall have been prominently developed.

Elementary Treatise on Physics, Experimental and Applied.

By Professor A. GANOT. Translated and Edited from the Ninth Edition, by E. ATKINSON, Ph.D., F.C.S. Part I. London: H. Baillière, 219, Regent Street.

This promises to be one of the best works on physics in the English language. The arrangement is methodical, the definitions clear and concisely expressed, and the illustrations profuse and to the purpose. The work is to be issued in monthly parts. The first part contains:—Book I. On Matter, Force, and Motion. Book II. On Gravitation and Molecular Attraction. Book III. On Liquids. It will be completed in about twelve parts and if the succeeding issues are equal to the one now before us, it will form a most valuable volume for the student.

NOTICES OF PATENTS.

564. *Cementation.* W. B. NEWTON, Chancery Lane, London. A communication. Dated March 5, 1861.

THE Patentee claims for the cementation of iron or steel the employment of alkaline carbonates, and, particularly, also the carbonates of baryta and of strontia, mixed with a certain quantity of powdered charcoal. This process is applicable whether the operation of the furnace be continuous or intermittent, and whether the treatment be conducted in reverberatory or in ordinary furnaces, or in steel melting crucibles. Under the head of carbonates, above-mentioned, the Patentee urges a distinct claim for the exclusive use of any other salts, which, under the influence of heat and the conjoint action of carbon and the nitrogen of the atmosphere, are capable of producing cyanides, which are in reality the agents operating in the conversion of iron into steel, and constitute the special basis of this process of cementation.

The theoretical views advanced in support of the patent claim are strictly in accordance with recent investigations

upon this subject; and the important assistance rendered in the process of cementation by the employment of cyanides has long been recognised.

576. *Preserving Animal or Vegetable Matters.* A. G. BRADÉ, Paris. A communication. Dated March 7, 1861. (Not proceeded with.)

THE specification describes a new method of preserving meat, fish, vegetables, &c., by virtue of the principle of endosmosis and exosmosis, which is carried out with the further object of abstracting a portion of the water naturally contained in these substances, and of keeping the said matters, thus partially dehydrated, sufficiently protected from actual contact with the atmospheric air. The mode of accomplishing this consists in immersing the articles of food to be preserved, for a moderate length of time only, in saline solutions or other suitable materials; they are then withdrawn and allowed to become surface-dry.

It is well known that methods of preservation have been based upon the exclusion of air by coatings of albumen and gelatin, and that if the meats have previously been soaked in brine their protection is rendered more certain; but there is, on the other hand, much evidence to show that beyond a comparatively short interval of time no reliance can be placed upon stores of provisions so treated.

577. *Preserving the Aroma and other Properties of Coffee and Cocoa from the Effects of the Atmosphere.* W. PRIDDING, Borough Road, Southwark. Dated March 7, 1861. (Not proceeded with.)

THE inventor first forms a packet of roasted and ground coffee or cocoa, or compound of either, by placing it in a mould and subjecting it to great pressure, so as to cause its particles to cohere. And after extracting such packet from the mould, he immerses it in a solution of gelatin, to which a small quantity of alcohol or methylated spirits of wine has been previously added. He then allows the prepared solution of gelatine to evaporate to dryness, and if needful dips the block of coffee or cocoa a second time, to increase the thickness of the coating, which should not be less than about one-thirty-second part of an inch. It is further recommended to surround the prepared coffee with an envelope of thin sheet gelatin, and to close the overlapping seams of this covering by moistening them with the solution of gelatin previously employed, and allowing them to dry. The objects secured by this proceeding are, firstly, the hermetically sealing the packet of coffee or cocoa as a means of preserving the aroma, and guarding against the deteriorating influence of the atmosphere; and, secondly, the gelatin will itself serve a useful purpose by refining the decoction in the process of making the coffee.

This invention is in principle very similar to that last described, and the remarks made in reference to the preceding specification are equally applicable to that now before us. It is questionable whether any external protective covering would be completely effectual in preventing decomposition or deterioration of ready-ground coffee on keeping for any length of time. The safer course, when coffee must be preserved, would surely be to roast and grind the berries as required.

583. *Improvements in the Mode of, and Apparatus used in the Process of Fermentation.* G. HOLLANDS, Rochester. Dated March 7, 1861. (Not proceeded with.)

THIS invention relates to certain arrangements whereby the beer in the fermenting vats or tanks is made always to stand at the same level, which is such that the yeast continually forming in the process of fermentation may conveniently deliver itself into the yeast vat placed below, and so avoid the necessity for frequent skimming and consequently exposing the surface of the beer.

The plan of making the yeast overflow into a separate vessel placed contiguous to the fermenting tun is one frequently adopted in breweries.

593. *Apparatus for Obtaining Gas.* J. JACOB, Golden Square, London. A communication. Dated March 9, 1861.

THIS invention refers to the production and employment of hydrogen gas. The specific claims of the patentee are as follows:—Firstly, the process of manufacturing hydrogen gas, on a scale suited for commercial purposes, by passing steam over red-hot iron filings or borings, or iron crushed, ground, or pulverised, as described. Secondly, the heating of the retorts or generators with the hydrogen gas produced in the process, combined with air and under pressure. Thirdly, the employment of the hydrogen gas and air, combined and under pressure, for heating and lighting purposes, and for all metallurgical operations.

The preparation of hydrogen according to a plan which is found described in all Manuals of Chemistry, and which has so frequently been put into operation on a moderate scale, can scarcely, we think, constitute a valid claim for a patent right; neither does the application to heating, lighting, and metallurgical purposes possess much originality; as proof to the contrary may be mentioned—Deville's gas furnace, the oxy-hydrogen blowpipe, the lime light, and the gas soldering apparatus frequently employed in uniting the plates of sheet lead used in the construction of sulphuric acid chambers.

Grants of Provisional Protection for Six Months.

1773. Thomas Cobley, Meerholz, Hesse, Germany, "An improved process for preserving and indurating timber, wood, and other vegetable matters, and for rendering the same unflammable."—Petition recorded July 15, 1861.

2312. Frederic Maitland Ransome and Ernest Leslie Ransome, Ipswich, Suffolk, "Improvements in treating stone, bricks, and other surfaces, and in the manufacture of filters."—Petition recorded September 16, 1861.

2335. James Cane Coombe and James Wright, Bridge Street, Blackfriars, London, "Improvements in the manufacture of stones, bricks, tiles, slabs, statuary, and such like materials, and in the method of and means for cleansing and indurating the same when employed in buildings or for building purposes, and for preserving them from atmospheric and other influences."

2348. Theophilus Redwood, Montague Street, Russell Square, London, "An improvement in the manufacture of paper."—Petition recorded September 19, 1861.

2489. Ebenezer Partridge, Patent Axle Works, Smethwick, Staffordshire, "Improvements in hardening iron and steel, and a composition or substance to be employed therein."

2525. Thomas Tidmarsh, Dorking, Surrey, "An improved artificial manure."

2526. John Schwartz, Osborne Street, Whitechapel, London, "An improvement in the manufacture of sugar."—Petition recorded October 9, 1861.

1547. Thomas Mellodew, Oldham, Charles William Kesselmeyer, Manchester, and John Mayo Worrall, Salford, Lancashire, "Improvements in dyeing and printing velvets, velveteens, and other fabrics with floated threads."—Petitions recorded June 17, 1861.

2526. John Schwartz, Osborne Street, Whitechapel, London, "An improvement in the manufacture of sugar."—Petition recorded October 9, 1861.

CORRESPONDENCE.

Specific Gravity and Solid Contents.

To the Editor of the CHEMICAL NEWS.

SIR,—The following samples of milk having come under my notice last week, I quote them as furnishing a very pertinent answer in the negative to your correspondent "Specific Gravity," in the CHEMICAL NEWS for August 10, 1861, who asks if it be possible in quantitative analysis of water, having obtained the specific gravity, to calculate from thence the total amount of solid contents in any volume, and *vice versa*, knowing these could you not calculate the specific gravity. However easily this may be done in the case of wine as shown, it is far otherwise with water, for instance, there being no rule of proportion to guide us. No. 1 sample of milk was of sp. gr. 1.031, and yielded per thousand grains, of dried curd 78 grains, of serum 82 grains; total, 160. No. 2 sample of milk was of sp. gr. 1.033! and yielded per thousand grains, of dried curd 50½ grains, of serum 49 grains; total 99½.—I am, &c.

JOHN HORSLEY.

Estimation of Alcohol in Wine.

To the Editor of the CHEMICAL NEWS.

SIR,—I accept, of course, without reserve, as absolute truth, the statement of Mr. Horsley in your last Number; and therefore can only point out as remarkable coincidences, that on the page (36 of Vol. I.) which contains the extract from Mulder, there is also a communication from Mr. Horsley; and further, that on page 108, and immediately following the first letter on the subject, there is again a communication from Mr. Horsley.

I am, &c. SUUM CUIQUE.

November 12, 1861.

MISCELLANEOUS.

Chemical Society.—The next meeting of this Society will take place on Thursday the 21st inst., at Burlington House. Chair taken at 8 p.m. A paper will be read by Dr. Bence Jones "On the Occurrence of Phosphate of Lime in the Human Urine."

Phosphorus in Oysters.—Mr. James Bruce writes to the *Mechanics' Magazine* as follows:—"Some little time ago, in the opening of an oyster, I was much surprised at observing a very bright flame about the centre, which, when examined a little closer, I found to proceed actually from a small quantity of real phosphorus; the quantity I could not ascertain, but there might be half a grain. I took it from off the oyster and immersed it in water, till I had an opportunity of observing it more minutely; which, when I did, I found it to be in every respect the same as the phosphorus obtained from bones, urine, &c. The oyster itself was perfectly alive and fresh, so that it could not happen from any decomposition of the constituent parts of the shell by the aid of putrefaction; it must have proceeded from some other source. As I have never read of this substance being furnished perfectly ready-formed in Nature, any elucidation of the subject from some of your numerous readers will be very acceptable. The circumstances, moreover, may serve to explain the accidental

poisoning from eating particular kinds of shell-fish; and again, those *cas rares* of 'spontaneous combustion' in the human body, as phosphorus, when heated, requires no more air than what is contained in the stomach to produce combustion which would perforate that organ."

Aureolin.—Under this name Messrs. Winsor and Newton are about to introduce to the public a magnificent yellow pigment, which supplies a desideratum hitherto in vain sought for by artists. It is the nearest approach to a perfect yellow in existence, and more closely resembles the purity of the prismatic spectrum than any other artificial colour. It is transparent, has great brilliancy and richness, both pure and in combination, and is very permanent, being entirely unaffected by exposure to sulphuretted hydrogen and other atmospheric impurities, or to the direct rays of the sun during an entire summer. Aureolin, with ultramarine and madder red, completes the triad of brilliant, permanent, and transparent primitive colours. We hope shortly to be able to lay before our readers a full description of the chemical as well as the artistic properties of this beautiful colour.

Relative Bulks of Snow and Ice.—In Sir Henry James' "Tables for the Reduction of Meteorological Observations," 1860, p. 30, are given the results of some experiments upon the conversion of ice and snow into water, conducted at Kingston, Canada West, February 28, 1854, in the presence of Lieutenant-Colonel Gordon, Lieutenant Farrell, Lieutenant the Hon. J. Bury, and Lieutenant Cox, Royal Engineers. In one experiment, one foot cube of ice was taken so pure and transparent that manuscript was perfectly legible through it. The average temperature of the block was zero, and its weight was 57 lbs. The lump was allowed to melt at a temperature of 52° Fahr., when it yielded ½ths of a cubic foot of water, or 1512 cubic inches, weighing 54 lbs. A corresponding experiment was then performed with virgin snow. One foot cube (1728 inches) was taken up soon after falling, and compressed into a cubic vessel; its average temperature was 19.5° Fahr., and its weight 63 lbs. 14 ozs. When melted at a temperature of 52°, it yielded 1728½ cubic inches of water, weighing 1021 ozs., or 63 lbs. 13 ozs. These remarkable results require verification in this country.

Conglomerate Copper.—The *Mining Gazette* (Lake Superior) states that in the Portage Lake District there is a belt of conglomerate which is remarkably rich in copper. It says:—"It is a singular fact, that nearly every belt of conglomerate within the trap range in this district, and we believe in the country, has more or less copper. This is a very marked and singular mineralogical feature, and offers a field for investigation for the geologist and mineralogist, of very great interest. The conglomerate has not been, as yet, in any country, put down as a metalliferous-bearing rock, and many questions arose on the discovery of the masses in the conglomerate belt at the Minnesota mine. It is still a question whether it may yet be more than the receptacle of mineral deposited from the real metalliferous rocks adjacent, which is a point of vast importance to the true knowledge of our veins, and is of great value in determining the value of a conglomerate lode, by a close examination of the overlying belts of trap, since the lodes are always over the conglomerate and are never under them."

ANSWERS TO CORRESPONDENTS.

Beta.—The fullest account of the various combinations of phosphoric acid and lime is to be met with in Gmelin's Chemistry, Vol. 3.
Hair Wash.—G. B.—The following has been recommended for this purpose:—Tinct. Cantharid 4 drms.; sp. ammon. co., 3 drms.; glycerin, 2 drms.; ol. rosmari, 20 minims, dissolved in sp. rectif. 1 drim; rose water or distilled water 7 ounces.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

On the Preparation of Urea from Ferrocyanide of Potassium, by M. CAREY LEA.

In the preparation of urea by Wöhler's method the amount obtained always falls short of that which should theoretically be produced. Having remarked that even when the operation is carefully performed with Liebig's proportions, the lixiviate always contains undecomposed cyanide of potassium, it occurred to me to try the effect of a more thorough oxidation, and the result proved very favourable. The following was the course adopted:—

Of roasted ferrocyanide of potassium 850 grammes are mixed with 318 grammes of thoroughly dried carbonate of potash in grains, and fused in an iron vessel. When decomposition is complete, the vessel is a little cooled, and 1900 grammes of red lead are to be added, not all at once, but 300 to 400 grammes at a time, with intervals of ten minutes, stirring and keeping up heat enough to retain the whole in a state of fusion.

After the last addition of red lead the mixture is suffered to remain half an hour on the fire to complete the reaction. Heat is applied in all for about four hours. In this way the cyanide of potassium becomes thoroughly oxidised. The process is concluded in the usual manner, and 500 grammes of urea are obtained. No particular precaution is necessary during the fusion, or even the lixiviation with cold water, but in evaporating the solutions the greatest care must be taken to carry off the vapours.—*Am. Journ. of Science*, No. xc.

On the Estimation of Tellurium, by M. H. ROSE.

Precipitation of Tellurium by Sulphurous and Phosphorous Acids.—Sulphurous acid is the best re-agent to precipitate tellurium from solutions of tellurous acid. For the precipitation to be rapid and complete, it is necessary to strongly acidulate the liquid with hydrochloric acid. Phosphorous acid, or rather phosphatic acid obtained by the slow oxidation of phosphorus in the air, can replace sulphurous acid in the precipitation of solutions of tellurous acid; the precipitation, however, is slower, even in the presence of an excess of hydrochloric acid, and the solution must be evaporated down several times successively in a water-bath to a syrupy consistency, and re-dissolved in water, to be sure of precipitating all the tellurium.

Reduction of Oxygen Compounds of Tellurium by Cyanide of Potassium.—M. Oppenheim, has already pointed out the employment of cyanide of potassium in fusion (*Journal für Praktische Chemie*,

vol. lxxi., p. 279), to reduce tellurium, and to separate this body from selenium. This process does not yield the theoretical quantity of tellurium, there is always more or less loss.¹ The most correct results are obtained by fusing the oxygen compound of tellurium at a gentle heat with cyanide of potassium in a long-necked flask, through which is passed a current of hydrogen. After fusing for about ten minutes, let it cool in the current of hydrogen, then fill up the flask with water, and turn it upside down in a beaker full of the same liquid. The telluride of potassium dissolves, colouring the water red; it decomposes in the air, depositing tellurium; this decomposition is hastened by passing a current of air through the solution. The deposited tellurium is collected on a filter, and the liquid, after addition of hydrochloric acid, is treated with sulphurous acid to reduce a small quantity of tellurous acid which may have been formed.

A boiling solution of cyanide of potassium only dissolves very little metallic tellurium. Telluro-cyanide of potassium is formed in this case. From this solution tellurium is precipitated by hydrochloric acid, but not by atmospheric air.

Reduction of Oxygen Compounds of Tellurium by Fusion with Alkaline Carbonates.—Instead of cyanide of potassium, alkaline carbonates can be employed, and especially a mixture of equal equivalents of carbonate of potassa and soda mixed with an equal weight of chloride of potassium or sodium in powder. The fusion cannot be performed in a flask, on account of the high temperature which is necessary; a porcelain crucible must be used, through which a current of hydrogen is passed.

This process gives less accurate results than the one in which cyanide of potassium is used.

Estimation of Tellurium in the State of Sulphide.—Tellurous acid is completely precipitated by sulphuretted hydrogen from its hydrochloric, or even nitric solution in the state of sulphide of tellurium; this may be dried at 100° and weighed: the nitric solution must contain no nitrous acid. If there is doubt respecting the purity of the sulphide of tellurium, it must be dissolved by chlorine in the presence of a small quantity of water, taking care to pass the chlorine which has traversed the sulphide of tellurium through a second vessel of water to avoid the loss of a small quantity of tellurium. When the solution is complete, dilute the liquid and heat it, to drive off chlorine; add hydrochloric acid to make sure that there is no fresh disengagement of chlorine, for all the telluric acid which has been formed must be completely transformed into tellurous acid before the tellurium is precipitated by sulphurous acid.

Estimation of Tellurous Acid by Simple Evaporation.—When tellurous acid is dissolved in other acids, especially nitric, it can be estimated by evaporating it on the water-bath and heating the dry mass in a platinum crucible to about 200° or 270°.

¹ M. Oppenheim has since modified his process by employing a boiling solution of cyanide of potassium, and using it simply to separate tellurium, selenium, and sulphur.—See CHEMICAL NEWS, Vol. III. p. 34.

If there is hydrochloric acid in solution, nitric acid must be added. Sulphuric acid may be completely driven off; but it is necessary to keep the mixture for some instants at the temperature of zinc.

Separation of Tellurium from Other Metals.—Tellurium cannot be separated by means of sulphide of ammonium from the metals whose sulphides are insoluble in this re-agent; tellurium always remains in the precipitated sulphides. It is necessary to employ in these cases the precipitation of tellurium from its solutions by sulphuric acid or the volatility of chloride of tellurium.

Separation of Tellurium from Sulphur.—Fuse the mixture of sulphur and tellurium with cyanide of potassium in an atmosphere of hydrogen; dissolve in water: tellurium soon separates from this solution in a metallic state. To estimate the sulphur, add potash to the liquid, and pass a current of chlorine through it, which transforms all the sulphur into sulphuric acid.

When the weight of the tellurium only in a mixture is wanted, oxidise with hydrochloric acid and chlorate of potash, heat the solution to drive off the chlorine, transform the telluric into tellurous acid by hydrochloric acid, and decompose the tellurous acid by sulphurous acid.—*Poggendorff's Annalen*, vol. cxii. p. 307.

Researches on the Relations existing between Atomic Weights, by M. J. S. STAS, Member of the Royal Academy of Belgium.

(Continued from page 259.)

Method of determining the Proportional Relation between Silver and the Chlorides.—I will now describe how I proceed with the determination of the proportional relation between silver and the chlorides. For this purpose I followed Gay-Lussac's process for the assay of silver by the wet way. This method has been already employed by M. de Marignac and by M. Pelouze. Almost all the last memoir of M. Dumas on the equivalents rests upon the method by the wet way.

In performing this I weighed either in air or in *vacuo* a certain quantity of chloride, and calculated and weighed the quantity of silver necessary, according to Prout's law, to precipitate the chlorine contained in the chloride. I took for silver 108; for chloride of potassium $39 + 35.5 = 74.5$; for chloride of sodium, $23 + 35.5 = 58.5$; and for chloride of ammonium, $4 + 14 + 35.5 = 53.5$. The excess of silver in the liquid after double decomposition, and the amount of this excess would yield me the relation between the proportional numbers of silver and the chlorides.

This is how I proceeded with the operation:—The silver, after having been heated to redness in a crucible of the same metal and properly cooled in the air, is weighed and introduced into a white glass flask, with the stopper well ground in with emery, and having very thick sides to enable it to withstand an internal pressure of at least ten atmospheres. I then pour upon the metal ten times its weight of pure nitric acid at 25° Baumé. I put in the stopper and fix it solidly in its place by the aid of strong cord. I then surround the flask with wire gauze, and place it in a bath where its temperature is raised to 45° or 50° C. At the end of twenty-four or thirty-six hours all the silver is dissolved without any trace of gas developing itself, and consequently without anything escaping from the flask. Indeed, the binoxide of nitrogen, as fast as it is produced, reduces the nitric

acid to the state of nitrous or hyponitric acids, which at this temperature remain perfectly dissolved in the large excess of nitric acid employed. If the temperature of the bath does not exceed 50° , there is really nothing to fear. I have made, under these conditions, and without any accident taking place, upwards of a hundred solutions of silver in a closed flask, employing from three to fifty grammes of silver at a time. Twice only, the temperature of the bath rising much too high, two flasks which were immersed in it yielded to the internal pressure and produced a rather violent explosion. I have had recourse to the solution of silver in a close vessel, because I have come to the conclusion that the method of solution in open vessels such as is adopted in the assay rooms of the Mint causes a slight loss of silver. I have seen assayers of proved skill obtain in three assays of the same silver results presenting greater differences than the errors which are due to the admirable method of Gay-Lussac. The same fact presented itself to me when I wished to familiarise myself with this process to prepare myself for the determinations. Moreover, the constant presence of silver in the washing-waters of the gas, arising from the solution of the metal during my syntheses of the nitrate and chloride of silver, sufficiently point out the necessity of effecting this solution either in a close vessel or in apparatus in which the escaping gases may be washed. I ought to add, however, that the loss experienced upon a gramme of silver never affects the accuracy of the assay of silver in the Mint, owing to the much more considerable and unavoidable error of experiment.

The solution of the metal having been effected, and the flask well cooled, I introduce such an amount of pure water that, with the acid already added, the total weight of the liquid becomes at the minimum thirty-five times, and at the maximum fifty times the weight of the silver employed. I now carry the flask into a dark room lighted with gas. After having conveniently inclined it, I introduce into it a tube, sealed up at one end, fixed to a rod of platinum, and containing the chloride weighed with the greatest accuracy which my balances will admit of. I then drop the chloride into the solution of silver, and wash the tube out several times with water, so as not to lose the traces of chloride which may remain adhering to it. After having tightly closed the flasks, and enveloped it in caoutchouc, I shake it until the liquid, at first turbid, becomes perfectly clear. I then proceed to the assay of the silver remaining unprecipitated. For this purpose, I have prepared with the greatest care the decimal solutions of salt and silver, such as are employed in the laboratories of the Mint.

On the other hand, I have myself manufactured pipettes, tubes which, when empty in a vertical position, would furnish me ten, five, four, three, two, one, or half a cubic centimètre of decimal solution. I also constructed bourettes, which, when placed in a vertical position, would deliver drops exactly equal to the twentieth of a cubic centimètre. The bourette itself and the tubes of half, one, and two centimètres, are subdivided into twentieths of a cubic centimètre. The small bourette consists of a graduated tube of four or five millimètres, internal diameter, drawn out to a point so as to expose an opening of about one millimètre in diameter, and melted to a larger open tube, the aperture of which is covered with a piece of vulcanised caoutchouc folded over the side of the tube, and more or less strongly bound to it, according as it is wished to deliver the drops more or less rapidly: my bourettes would only give five or six per minute.

If there is hydrochloric acid in solution, nitric acid must be added. Sulphuric acid may be completely driven off; but it is necessary to keep the mixture for some instants at the temperature of zinc.

Separation of Tellurium from Other Metals.

—Tellurium cannot be separated by means of sulphide of ammonium from the metals whose sulphides are insoluble in this re-agent; tellurium always remains in the precipitated sulphides. It is necessary to employ in these cases the precipitation of tellurium from its solutions by sulphuric acid or the volatility of chloride of tellurium.

Separation of Tellurium from Sulphur.—Fuse the mixture of sulphur and tellurium with cyanide of potassium in an atmosphere of hydrogen; dissolve in water: tellurium soon separates from this solution in a metallic state. To estimate the sulphur, add potash to the liquid, and pass a current of chlorine through it, which transforms all the sulphur into sulphuric acid.

When the weight of the tellurium only in a mixture is wanted, oxidise with hydrochloric acid and chlorate of potash, heat the solution to drive off the chlorine, transform the telluric into tellurous acid by hydrochloric acid, and decompose the tellurous acid by sulphurous acid.—*Poggendorff's Annalen*, vol. cxii. p. 307.

For this purpose I followed Gay-Lussac's process for the assay of silver by the wet way. This method has been already employed by M. de Marignac and by M. Pelouze. Almost all the last memoir of M. Dumas on the equivalents rests upon the method by the wet way.

In performing this I weighed either in air or *in vacuo* a certain quantity of chloride, and calculated and weighed the quantity of silver necessary, according to Prout's law, to precipitate the chlorine contained in the chloride. I took for silver 108; for chloride of potassium $39 + 35.5 = 74.5$; for chloride of sodium, $23 + 35.5 = 58.5$; and for chloride of ammonium, $4 + 14 + 35.5 = 53.5$. The excess of silver in the liquid after double decomposition, and the amount of this excess would yield me the relation between the proportional numbers of silver and the chlorides.

This is how I proceeded with the operation:—The silver, after having been heated to redness in a crucible of the same metal and properly cooled in the air, is weighed and introduced into a white glass flask, with the stopper well ground in with emery, and having very thick sides to enable it to withstand an internal pressure of at least ten atmospheres. I then pour upon the metal ten times its weight of pure nitric acid at 25° Baumé. I put in the stopper and fix it solidly in its place by the aid of strong cord. I then surround the flask with wire gauze, and place it in a bath where its temperature is raised to 45° or 50° C. At the end of twenty-four or thirty-six hours all the silver is dissolved without any trace of gas developing itself, and consequently without anything escaping from the flask. Indeed, the binoxide of nitrogen, as fast as it is produced, reduces the nitric

acid to the state of nitrous or hyponitric acids, which at this temperature remain perfectly dissolved in the large excess of nitric acid employed. If the temperature of the bath does not exceed 50° , there is really nothing to fear. I have made, under these conditions, and without any accident taking place, upwards of a hundred solutions of silver in a closed flask, employing from three to fifty grammes of silver at a time. Twice only, the temperature of the bath rising much too high, two flasks which were immersed in it yielded to the internal pressure and produced a rather violent explosion. I have had recourse to the solution of silver in a close vessel, because I have come to the conclusion that the method of solution in open vessels such as is adopted in the assay rooms of the Mint causes a slight loss of silver. I have seen assayers of proved skill obtain in three assays of the same silver results presenting greater differences than the errors which are due to the admirable method of Gay-Lussac. The same fact presented itself to me when I wished to familiarise myself with this process to prepare myself for the determinations. Moreover, the constant presence of silver in the washing-waters of the gas, arising from the solution of the metal during my syntheses of the nitrate and chloride of silver, sufficiently point out the necessity of effecting this solution either in a close vessel or in apparatus in which the escaping gases may be washed. I ought to add, however, that the loss experienced upon a gramme of silver never affects the accuracy of the assay of silver in the Mint, owing to the much more considerable and unavoidable error of experiment.

The solution of the metal having been effected, and the flask well cooled, I introduce such an amount of pure water that, with the acid already added, the total weight of the liquid becomes at the minimum thirty-five times, and at the maximum fifty times the weight of the silver employed. I now carry the flask into a dark room lighted with gas. After having conveniently inclined it, I introduce into it a tube, sealed up at one end, fixed to a rod of platinum, and containing the chloride weighed with the greatest accuracy which my balances will admit of. I then drop the chloride into the solution of silver, and wash the tube out several times with water, so as not to lose the traces of chloride which may remain adhering to it. After having tightly closed the flasks, and enveloped it in caoutchouc, I shake it until the liquid, at first turbid, becomes perfectly clear. I then proceed to the assay of the silver remaining unprecipitated. For this purpose, I have prepared with the greatest care the decimal solutions of salt and silver, such as are employed in the laboratories of the Mint.

On the other hand, I have myself manufactured pipettes, tubes which, when empty in a vertical position, would furnish me ten, five, four, three, two, one, or half a cubic centimetre of decimal solution. I also constructed bourettes, which, when placed in a vertical position, would deliver drops exactly equal to the twentieth of a cubic centimetre. The bourette itself and the tubes of half, one, and two centimetres, are subdivided into twentieths of a cubic centimetre. The small bourette consists of a graduated tube of four or five millimetres, internal diameter, drawn out to a point so as to expose an opening of about one millimetre in diameter, and melted to a larger open tube, the aperture of which is covered with a piece of vulcanised caoutchouc folded over the side of the tube, and more or less strongly bound to it, according as it is wished to deliver the drops more or less rapidly: my bourettes would only give five or six per minute.

It is absolutely necessary to hold the bourettes in a vertical position, for the same instrument which furnishes with the greatest accuracy twenty drops per cubic centimetre only delivers seventeen or eighteen when it is inclined 45° ; in a position of 10° or 15° no more than sixteen or seventeen drops are required to make a centimetre.

To perform the assay, I had besides the following arrangement:—In a long narrow box, the anterior portion of which was furnished with yellow glass, and the posterior portion lighted by a gas lamp, I arranged a perfectly spherical glass globe containing a saturated solution of the double chromate of potash and soda, so as to concentrate the rays and obtain a cone of yellow light. I then place the flask containing the assay in such a position that the surface of the liquid may be traversed by the beam of yellow light. To make an observation, I place myself so as to make an angle of 60° with the luminous ray traversing the flask. When this artifice is employed, a liquid containing two milligrammes of silver per litre produces a yellow opaque and dull precipitate of chloride of silver, when half a centimetre of decimal solution is allowed to fall carefully upon its surface; when the quantity of silver is reduced to one milligramme, the precipitate of chloride is yellow, opaque, and brilliant; when the liquid is diminished in strength, so that it contains no more than the twentieth of a milligramme of silver per litre, there is still produced an appreciable cloud upon the addition of a corresponding quantity of decimal solution. It is only necessary to wait sufficiently long, without touching the flask, to be certain of it. Nevertheless, in these assays I have only worked to tenths of a milligramme.

In all my experiments I have continued adding decimal salt solution as long as I have seen a cloud produced on the surface of the liquid after standing fifteen minutes. When I have arrived at the extreme limit, and have just passed it, I add five centimètres of decimal solution of silver. After well shaking, I neutralise three-quarters of the excess of silver, so as to obtain immediately upon agitation a clear liquid approaching very nearly the extreme limit. When there was a difference between the results of two assays, a difference that has never exceeded two or three tenths of a milligramme, I always took the minimum result.

Those who have made many assays by the wet way will have noticed that the interior sides of a flask in which they have shaken for some time chloride of silver

produced by successive precipitation, becomes covered with a kind of varnish of chloride, appears greasy, and so loses its transparency. To obviate this inconvenience when it occurs, I remove, by means of a pipette, a portion of the liquid after it has been agitated and become limpid by standing sufficiently, and transfer it to a bottle having parallel sides of crystal, and ascertain in this second bottle the presence of silver or salt in excess. The liquid in this bottle was always added to the first whenever it was found necessary to continue the operation.

The assay presents another difficulty which may lead one greatly in error when not forewarned of it.

A liquid from which there has been precipitated by a saline solution almost all the silver, but which still contains between one and two milligrammes of silver per litre, is precipitated equally upon the addition of a decimal solution of silver or of salt. In this case, however, there is a very evident difference in the resulting turbidity. The precipitate occasioned by the decimal salt solution to the assay containing one or two milligrammes of silver in the state of nitrate is always opaque, yellow, and brilliant; whilst the precipitate formed upon the addition of nitrate of silver to the same liquid is whiteish and translucent. I account for this anomaly by the slight solubility of chloride of silver in the alkaline nitrate in solution, and which precipitates in the presence of a silver solution richer than itself. I have, notwithstanding, always added decimal salt solution until precipitation ceases.

Such is the method of assay which I have adopted for all my determinations by means of double decomposition.

I now return to the chloride of potassium.

I have made two series of determinations: the first was performed nearly three years before the second. I separate the results because three of the five experiments composing the first series were performed with silver prepared by Gay-Lussac's process. The silver of Number I. underwent one treatment, that of Number II. two treatments, and that of Number III. three treatments. This silver is not pure, as I have already said; but, as I carefully ascertained the standard of that which I employed, by comparing it with metal obtained by electrolysis, or by Liebig's process, I was able to submit its weight to the necessary corrections. These three determinations show better than any argument how much impurity in the metal can affect the result. It is only with this object that I publish them. The nineteen

(1) Thus in the original paper: it is evidently a misprint for 11.74373.

experiments composing the second series are more than sufficient to establish the true proportional relation between silver and chloride of potassium.

The last two determinations of the first series were performed with silver obtained, in Number IV. with divided phosphorus and an excess of pure nitrate of silver, and in Number V. by the decomposition of acetate of silver crystallised a great many times, and, moreover, prepared with silver previously purified.

The chloride of potassium employed in the five determinations of the first series was the same, and was derived from the analyses of chlorate of potash, which I describe further on. The traces of silica and alumina were separated from it by the means already given. The solution was neutral, and yielded a liquid of absolute limpidity.

The silver employed for the determinations of the second series has been prepared either by electrolysis or by Liebig's process, or by the decomposition of pure chloride with carbonate of soda. All the silver was compared with the purest which I had been able to procure by the methods already indicated. The metal employed in experiment Number VII. was prepared by M. Liebig.

TECHNICAL CHEMISTRY.

On the Occurrence of Gold in Wales,
by T. A. READWIN, Esq.¹

I SHALL confine my observations in this paper to an area of about twenty square miles, situated north of the

¹ Read before the British Association.

turnpike road leading from Dolgelly to Barmouth. Professor Ramsay has so ably described the geology of this district, in a communication to the Geological Society of London in 1854, entitled "The Geology of the Gold-bearing Districts of Merionethshire," that I shall merely refer to its geology for the information of those present who have not perused the communication referred to. The Dolgelly district is bounded by the river Mawddach, the great Merioneth anticlinal range, and the little river Camlan. In this district are found the Cambrians, overlaid by the lower Silurian lingulas. The Cambrian rocks are coarse greenish-grey grits, and the lingula flags are arenaceous slaty beds, interstratified with courses of sandstone. Calcareous and greenstone dykes frequently penetrate both the Cambrian and the Silurian rocks. The metalliferous products are chiefly argentiferous galena, copper pyrites, blende, manganese, and mundic, associated frequently with gold. According to Sir R. Murchison, the most usual position of gold is in quartzose veinstones that traverse altered palaeozoic slates, frequently near their junction with eruptive rocks, whether of igneous or of aqueous origin. The stratified rocks of the highest antiquity, such as the oldest gneiss or quartz rocks, have seldom borne gold; but the sedimentary accumulations which followed, or the Silurian, Devonian, and carboniferous (particularly the first of these three), have been the deposits which, in the tracts where they have undergone a metamorphosis or change of structure, by the influence of igneous agency or other causes, have been the chief sources whence gold has been derived. After referring to the opinion of Professor Ramsay that gold in the Ural Mountains, Australia, &c., occurred in rocks of a similar age and character, Mr. Readwin continued: Sir R. Murchison's statement is

singularly corroborated by the position of the quartzose vein in the Clogau Mine, distinguished as the "gold lode," which traverses altered palaeozoic slates, near the junction of an eruptive bar of porphyritic greenstone; and the same law appears to obtain, also, with respect to all gold-bearing quartzose veins of the Dolgelly district, upon the ores of which I have made a very large number of experiments during the past eight years. There are in this district about twenty localities in which gold has been discovered visible, in quartz or associated, more or less with galena, blende, copper pyrites, telluric-bismuth, carbonate of lime, schist, baryta, iron pyrites, &c. By far the richest discoveries of gold have been made at the Dol-y-frwynog, Prince of Wales, Cambrian, and the Clogau mines. Gold has also been found in the "marine drift" by the Hon. F. Walpole, Sir Augustus Webster, myself, and others, a piece of which is now on the table. Mr. Arthur Dean, in a paper read before the British Association in 1844, stated that a complete system of auriferous veins exists throughout the whole of the Snowdonian or Lower Silurian formations of North Wales. Upon the faith of this, much money was spent at the Cwmheisian mines, and very little gold obtained by smelting operations, for reasons which are now not very difficult to understand. Much money was also spent about ten years afterwards at the same place, after setting the most eminent assayers to work to prove the truth of Mr. Dean's statement, in erecting machinery, which produced even less gold by amalgamation than the former method; although it was then held as an axiom, that gold always exists in a metallic state, that mercury has always an affinity for gold, and, therefore, wherever gold is present in minerals mercury will necessarily dissolve it. In this instance, however, this did not prove the case, and the result of operations upon 150 tons came at length to be considered as an enigmatical failure, as the following extracts from the experiments made at the time will show. [Here followed a detailed account of experiment No. 7, made on $4\frac{1}{2}$ tons of metalliferous minerals, which was triturated in 42 lbs. of mercury.] Ten pounds of this, on distillation, gave 70 grains residual metal, containing 184 grains of gold. A qualitative analysis of this residual metal gave gold, silver, lead, bismuth, zinc, arsenic, and also traces of copper and iron. The distilled mercury contained traces only of zinc and arsenic. It had been proved before the experiment, and also since, that the $4\frac{1}{2}$ tons of mineral contained several ounces of this "royal metal," but the quicksilver neglected it for associates of less dignity, though intrinsically of more real utility. This, however, was not the result expected. At the Dol-y-frwynog mine, about two years afterwards, Sir Charles Price operated similarly upon several tons of material, but with the same provoking failure as before. At present the Clogau mine is the most interesting and profitable. It stands at an elevation of 1000 feet above the level of the sea. The "Saint David's," or "Gold Lode," is the most remarkable feature. After giving some interesting descriptions of this mine, the author desired to notice especially that this lode is at the junction of the Cambrian sandstones and the lingula flags of the Lower Silurian rocks. A quantity of what was called "poor copper ore;" was raised from this lode and sold many years since; but in 1854 the refuse of this "poor copper ore" was examined, and indications of "native gold in considerable quantities" were found. Some of this refuse ore was put to the test, and in one instance, to his knowledge, 100 lbs. weight yielded 14½ ounces of gold. Many other experiments have been made by various persons with equal success, but owing

to the uncertainty of the operation of amalgamation, on the one hand, and the mines themselves being subject to two Chancery suits on the other, the general value of the lode, in bulk, has not until recently been determined. After some observations on the processes of assay,—which he did not think would give the approximate value of auriferous minerals, notwithstanding that the contrary had been asserted by many eminent men,—the author referred to a series of thirteen experiments, made by himself last autumn upon 112 lbs. of auriferous quartz from the Clogau Mine, duly prepared and sampled by Johnson and Son, of London. The whole quantity gave 25 oz. 16 dwts. 7 grains of amalgam, and of fine gold, 8 oz. 5 dwts. 19 grains. A gentleman of high standing in such matters had declared the value of the gold by assay to be 9½ per cwt., while he (Mr. Readwin) declared it to be 30½, so he (Mr. Readwin) happened to be right, as he had operated upon samples of 7½ lb. each, instead of the usual 400 grains. He would now state the result of actual working operations for gold at the Clogau Mine since the beginning of the year. This statement showed that 207 tons 8 cwt. of quartz gave 1314 ounces of fine gold; 3 tons of the best of this quartz gave no less than 9766 ounces of gold. If they added 56 ounces obtained from 5 tons in 1860, it showed a total quantity of 1370 ounces of gold from 212 tons of auriferous mineral, being at the rate of 6½ ounces per ton. This he believed was the first instance of a hundredweight of gold having been obtained from the Crown lands of this country, the value of which was 5300½. This "Royal mine" paid a royalty of $\frac{1}{16}$ th to the Crown. The cost of extraction had been very inconsiderable, and there was a probability of an equal yield of gold for some time to come. Mr. Readwin concluded by saying:—Seven years ago I determined, unwisely perhaps, never to leave this vexed question until I had mastered it. I have done so. Experiments are ended, works are the result of faith, and, after great wear of both mind and body, I have proved what many then doubted, and many more derided, that gold does really exist in the Dolgelly district, and that it can be extracted from the minerals in remunerative quantity. I am very glad to have had the opportunity of stating this to the British Association, under the presidency of the sagacious Director-General of the Geological Survey of Great Britain.

Mr. Jukes said he was sure they were all much obliged to Mr. Readwin for his very clear and lucid statement relative to the gold in North Wales. They had long known of its existence, but not that it existed in sufficient quantities to render its production remunerative.—Professor Smith, of Sydney, Australia, asked Mr. Readwin by what process he separated the gold from the quartz?—Mr. Readwin: Chiefly by amalgamation, taking care not to intrude any mineral that would have the effect of neutralising the mercury, as galena or copper pyrites, &c.—Professor Smith inquired whether some of the mercury was not lost in the process?—Mr. Readwin stated that some of the mercury was always lost; it became so finely divided that some of it was sure to be carried away.—Mr. Smith said he perceived that in old North Wales they were falling into the same difficulty as their friends in New South Wales. There were many things which would have a singular action upon mercury, and likely to injure its effect on the gold. The action they had was a chemical one, and, therefore, the gold-producers of New South Wales had depended, to a great extent, upon mechanical action exclusively, and generally they had been very successful. If anyone

could point out any means by which gold could be satisfactorily separated from the quartz, it would be a great boon. The mechanical means they employed in New South Wales would leave only half-an-ounce per ton, which was considered very fair. The production of gold in old North Wales, as detailed by Mr. Readwin, surprised him very much. The yield of gold in Victoria or New South Wales did not exceed one ounce per ton of quartz, and in many instances half-an-ounce was considered a fair yield. The digger of Australia would be extremely proud to get it in such quantities as six ounces per ton, as Mr. Readwin had stated the yield of the Dolgelly quartz to be. From three to four ounces per ton would be considered very good anywhere in the gold districts of Australia. In some small localities the yield had been as high as thirty ounces, forty ounces, or even more, per ton, but they were exceptional, and did not last long.—In answer to another question, Mr. Readwin stated that the actual cost of obtaining the 1300 ounces of gold was under 300*l*. He did not wish there to be any misunderstanding as to the yield of gold, for taking an average of the whole auriferous district of Dolgelly, he did not suppose the yield would be above half-an-ounce per ton.—A gentleman asked what was the cost per ton of crushing the quartz?—Mr. Readwin said that as they worked only by water power, the cost of crushing per ton would be less than half-a-crown.—Professor Smith expressed his surprise, as the cost per ton in Australia was calculated on an average at 1*l*. per ton. He referred to the fact that most of the firms there used the Cornish stampers for crushing the quartz, and that it answered its purpose well.—Mr. Readwin did not approve of the stampers, as he had found gold washed away after their use.

PHARMACY, TOXICOLOGY, &c.

On the Employment of Arseniuretted Alcohol for the Preservation of Objects of Natural History, especially Insects, by M. LEPRIEUR.

At the ordinary temperature pour 500 grammes of rectified alcohol, weighing at 94 per cent. on an excess of opaque arsenious acid. After eight hours of contact, during which time the liquid is frequently shaken, the alcohol is filtered. Upon evaporating 200 grammes of the solution in a platinum capsule over a water-bath, a residue is left weighing 0.03 grammes, or 0.15 grammes per kilogramme. On employing alcohol at 85 per cent. a residue is left of 0.102 grammes, or 0.51 grammes per kilogramme. If the alcohol at 85, and the arsenious acid, are kept in contact for four months, the residue weighs 1.38 grammes per kilogramme.

To be as energetic and complete as possible, the action of the arseniuretted alcohol should take place on tissues very recently deprived of life: it is, consequently indispensable in the case of insects, for example, that they should be immersed in it whilst still alive, or, better still, after having been asphyxiated with the vapour of ether, chloroform, or benzole. Some of them, indeed, must not be immersed living in even pure alcohol, for as soon as they touch the liquid they open their elytra and spread their wings as if they wished to fly away.

Almost all the coleoptera, the hemiptera, and even the orthoptera, can be plunged without danger into the arseniuretted alcohol, provided they are not left in longer

than ten or twelve hours; after this time they must be taken out of the alcohol and thrown upon blotting-paper, then they are to be pricked or cemented down until they have lost by evaporation the greater part of the liquid.

When the insects have been allowed to dry before being plunged into arseniuretted alcohol, the action of the latter is not so efficacious; when a collection is much attacked by larva, recourse must be had to an immersion for twelve hours.

Of all the methods which have been proposed to preserve collections, this is, according to M. Leprieur, the best. He has employed arseniuretted alcohol for twelve years, to the exclusion of all other means, and with uniformly good results.

It follows from M. Leprieur's experience that living insects, plunged into arseniuretted alcohol, and removed after remaining there for twelve hours only, increase in weight by about one-fourth; insects, therefore, preserve in their organs an amount of arsenious acid about equal to $\frac{1}{1000}$ of their own weight, a quantity quite sufficient to protect them from destruction by larvæ.

According to M. Leprieur, the employment of an alcoholic solution of arsenious acid possesses the advantage of preventing, in an almost absolute manner, the ravages of larvæ, whilst all other means, whatever be their efficiency, can have no other result than the actual destruction of the larvæ already present in a collection, without having any power to protect them from future ravages.—*Journal de Pharm. et de Chim.*, vol. xxxix. p. 435.

PHYSICAL SCIENCE.

On Phosphorescence, by M. DE REICHENBACH.

THE experiments of M. De Reichenbach tend to prove that phosphorescence is a usual consequence of all molecular phenomena, and not the result of combustion or oxidation. Mr. Phipson proved this last point some time ago, when he showed that dead fishes shine in the dark, even under water, and in the absence of oxygen.

According to M. De Reichenbach there is phosphorescence during fermentation or putrefaction, crystallisation, evaporation, condensation of vapours, the production of sound (vibrations therefore), and the fusion of ice; a considerable glow is remarked when a galvanic pile in activity, a block of ice in fusion, or a solution of sulphate of soda in the act of crystallising is observed in the dark.

The human body itself is not devoid of phosphorescence: in a healthy state it emits a yellow glow; when in ill-health the glow becomes red. The author considers that this observation may possibly be of use in diagnosis.

To perceive these phenomena the eye ought to have been previously rendered sensitive by remaining some hours in perfect darkness, and even then all eyes are not equally impressionable. But, if several persons unite in performing the experiment together, there will always be a certain number who are able to see the phenomena.

These facts of the production of light remind the author of observations published some time ago, by M. Wullner, according to which every molecular movement is accompanied by a disengagement of electricity.—*Poggendorff's Annalen*, vol. cxii., p. 459.

PROCEEDINGS OF SOCIETIES.

PHARMACEUTICAL SOCIETY.

Wednesday, November 6, 1861.

Mr. P. SQUIRE, President, in the Chair.

Professor BENTLEY exhibited a specimen of the Ordeal Root spoken of by M. du Chaillu in his book on Western Africa. It is there said to be in use among some African tribes as a test for witchcraft—an individual suspected of that crime being required to imbibe a strong infusion of the root. It is intensely poisonous, and if the individual dies he is supposed to have been guilty, but if, from any cause, he should survive the ordeal, he is considered innocent. The observed effects of the poison, and the character of the bark on the root, the Professor said, left no doubt on his mind that it was derived from a species of *strychnos*.

Mr. BROWN received the silver medal of the Society for a magnificent herbarium, consisting of 776 specimens of British plants. Several of the specimens were exhibited, and the preservation and mounting of the plants excited great admiration.

The PRESIDENT then read a Paper On Medicinal Extracts, taking Extract of Belladonna as an Example. The object of the Paper was to point out that the process for the preparation of the so-called green extracts, given in the London Pharmacopœia for 1851, was never followed by the manufacturers of those extracts on a large scale; and, further, that the plan which is adopted by the manufacturers is decidedly the better. Mr. Squire tested the different processes with some belladonna. The plant arrived at maturity in September this year, and was then cut, and immediately used. From this plant three extracts were made, one from the leaves only, as directed in the Pharmacopœia, another from all the soft parts (the plan adopted by the manufacturers), and a third from all the soft parts except the leaves. The first became mouldy in ten days. Both the others were good extracts, which kept well. To test the effects of the extracts, Mr. Squire placed specimens in the hands of some eminent ophthalmic surgeons—Mr. Wordsworth, Mr. White Cooper, and others—for trial, and they all reported that the extract made from the soft parts without the leaves acted most powerfully and rapidly in dilating the pupil of the eye. Mr. Squire concludes, therefore, that the most active and best keeping extract is made from the whole of the soft parts of the plant—a fact which applies to extract of henbane and other green extracts as well as belladonna. Another reason for adopting the manufacturers' plan was, that when the Pharmacopœia process was followed, there was a loss of one-third of the useful constituents of a plant.

Mr. DEANE said that *a priori* it was a serious mistake to reject the succulent stalks of plants like belladonna in making extracts, for the sap passed from the leaves to the stems, and there formed active substances. And this was the case, not only in succulent, but woody stems, and even roots, as had just been shown in the ordeal root. He had made extracts in all sorts of ways, evaporating *in vacuo*, by continuous boiling, and by evaporation at a low temperature; and he found that an extract evaporated without coagulating the albuminous matter kept without moulding if the plant was gathered in proper condition, but if the albuminous matter was coagulated, the extract became mouldy in a short time. An extract boiled down he also found to keep well and exhibit no tendency to mouldiness; and further, there was not the same disposition to ferment as was sometimes seen in extracts made at a low temperature. A great point in making a good extract was to make use of the plant at once before any heating took place. The effect of this heating was well

shown in the case of tea, the difference between black and green tea simply being, that in the former the leaves were allowed to heat before they were dried, and to make green tea the leaves were dried as soon as picked. Some change of the same sort took place in all plants, and the best and most elegant extracts were made from herbs gathered at the proper time and not allowed to heat. Plants in incipient inflorescence, or even one-third flowered, were unfit for extracts. The older they were, the less albuminous matter they contained.

Mr. HEATHFIELD said that the juice from stalks contained as much active matter as that from leaves. Fermentation, he said, took place in extracts where chlorophyll was absent, as in the extracts of broom, colchicum, and poppies; but when chlorophyll is present it never takes place. An extract from the stalks alone he found to liquefy soon. He agreed with Mr. Deane that the best extract was made from a plant of which the flowers were fully formed, and all the soft parts, leaves, flowers, seed-vessels, and branches were used. Such an extract would keep good an unlimited time. In 1831 he experimented with the juice of hemlock. He separated the albuminous matter and chlorophyll, and found that these in summer weather moulded very soon, while the juice kept well. In examining the juice to try and discover what had kept it, he found a considerable amount of chloride of sodium, which he believed was the cause. He had found no difference in the keeping properties of extracts made at different temperatures.

Mr. FRANCIS said he always used all the soft parts of the plants. The best extracts were made by evaporating in-doors to the consistence of treacle, and finishing out in the sun. In that manner an extract was obtained of the finest flavour, and which would not become mouldy. It was a mistake to make green extracts; they were brown when made in the sun.

Mr. HASELDEN said he had made extracts according to the Pharmacopœia process, which he found to keep very well, and have the true aroma, but which had not the consistence of extracts made from the whole plant. They absorbed moisture, and were unfit for making pills.

Mr. HOLLAND said that, as a large manufacturer, he had found it dangerous to allow the plants to ferment before making the extracts. He used all the soft parts that could be easily broken by the hand. He had noticed that the chlorophyll separated at one heat, and the albuminous matters at another.

Professor BENTLEY said that practical men, without an exception, never made extracts from the green leaves alone, but used all the parts of a plant in close contact with the leaves, which were essentially the same as leaves. The Pharmacopœia process could not be followed because an extract made from the leaves never kept, but became mouldy in a few weeks. Allowing the plants to heat was highly objectionable. The extract should be made immediately after the plants were gathered.

Mr. HILLS read some statistics. From about 1 cwt. of the belladonna plant, of which perhaps three-quarters were thrown away, he in the following years obtained the following amounts of extract:—1859, 1lb. 9½ozs.; 1860, 1lb. 10½ozs.; 1861, 2lbs. 4ozs.

The further discussion of this subject was adjourned until the next meeting.

Mr. FURLEY then exhibited his "Process for Rendering Pills Tasteless." He was provided with two saucers. Into one of these he put some powder composed of equal parts of tragacanth and sugar. The inside of the other he smeared with white of egg which had been well shaken and poured away from the froth. The pills were first placed in this latter saucer, which was then moved rapidly round and round, causing the pills to revolve within, by which means they in a second or two became covered all over with a film of albumen. They were then transferred to the other saucer and again made to revolve in the

powder, which now adhered to the albumen, and so the pills became coated with a mixture of tragacanth and sugar.¹

Mr. ATTFIELD afterwards exhibited, and explained the principle of, Casella's Minimum Thermometer, an account of which instrument has already appeared in the *CHEMICAL NEWS*.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, November 12, 1861.

Dr. R. ANGUS SMITH, *Vice-President, in the Chair.*

Mr. Thomas Coward was elected an ordinary member.

Mr. E. W. BINNEY said that some years since he read a paper before the Society, "On the Drift Deposits found near Blackpool," which was afterwards printed in Vol. X. (new series) of the *Memoirs*. In the gravel at Bispham, most probably the high level gravel of Mr. Prestwich, he found nineteen species of shells, all identical with those now found in the Irish Sea. He also stated that in the lowest bed of till there found, full of scored and striated rocks, he collected shells of the genera *turritella*, *buccinum*, *nassa*, *dentalium*, *nucula*, *cardium*, and *tellina*. Owing to such shells found in these deposits not having so arctic a character as those said to be found in other till beds, it has been supposed that they are of a more recent date than the glacial age of Forbes, or the pleistocene of Lyell. Professor King, of Queen's College, Galway, a geologist of high reputation, in his *Synoptical Table of British Aqueous Rock Groups*, &c., just published, classes the Blackpool fossils with post-pleistocene, as shell sands occurring just under deposits now forming around the shores of the British Islands, and immediately above the Devonshire raised beaches. The Blackpool gravels, near Bispham, are as good pleistocene as can be found in any of the high level gravels met with further inland, notwithstanding the fossils discovered in them, which are of the same kind, although not so numerous, as those met with in the gravels of Bowdon, Cheshire, and the sands of Haigh, Lancashire. He also said that the lowest bed of till seen at Blackpool, and containing the shells previously alluded to, had all the physical characters of the Scottish, Irish, and North of England iceberg and glacial drift, and had been subject to considerable elevations since its deposition.

Mr. R. D. DARBISHIRE said that he had lately found under undisturbed clay at a considerable elevation on the southerly slope of Great Orme's Head, a deposit of bones of different mammalia intermixed with shells of *mytilus*, *littorina* and *patella*. He hoped to lay the results of further observations before the Society on a future occasion. He supposed the deposit might be connected with the present or past existence of some "bone cave" in the limestone rock of the Head. He suggested, however, that possibly the bones and shells may have been the remnants of the cookery of former inhabitants of the district, and referred, in illustration, to the researches made amongst the *Kjokkenmøddings* on the coasts of Denmark.

Dr. JOULE, in reference to speculations on the thickness of the earth's crust, stated that he had some time ago received a letter from Professor Thomson, giving an account of the progress of investigations calculated to throw light on this interesting subject. Professor Thomson finds that

the equilibrium lunar tide in a solid glass globe (without mutual gravitation) of the same size as the earth is about five feet. Hence, from the phenomena of the actual tides of the ocean, it follows that the earth, as a whole, is more rigid than glass. The observations of Mallet, with experimental earthquakes, show that the earth's crust is many times less rigid than glass. Hence Professor Thomson infers that the earth, as a whole, is many times more rigid than the rocks and strata on its surface.

Dr. CRACE CALVERT stated that he wished to draw the attention of the manufacturing chemists of this district to a very simple and rapid method which had been devised by the eminent chemist M. Pelouze, Master of the Paris Mint, for determining the amount of sulphur existing in pyrites. He (Dr. Calvert) was induced to do so, believing that any process which would simplify the long and troublesome operations now followed to ascertain the value of this mineral would be useful to many members now present at this meeting. The process consists in mixing intimately together one part of pyrites, thoroughly pulverised in an agate mortar, with five parts of carbonate of soda, seven parts of chlorate of potash, and five parts of chloride of sodium, and placing the whole in an iron spoon, which is gradually carried to a dull red heat. The mass, when cold, is first washed with cold water and then with boiling water, until the whole of the soluble matter is removed; and this solution is tested with a standard solution of sulphuric acid. As 100 grains of carbonate of soda requires 92.45 of monohydrated sulphuric acid, or SO_3H_2 , it follows that the quantity of soda in the carbonate of soda employed will decrease in proportion to the quantity of sulphur from the pyrites converted into sulphuric acid, which will have neutralised a corresponding quantity of the soda in the carbonate.

This mode of assaying is so simple, that the Author states that he can determine, within one or one and a-half per cent., the value of a sample of pyrites, in the space of an hour's time.

M. Pelouze also states that by employing the following proportions of the same materials, the manufacturer can determine the amount of sulphur in burnt pyrites. Five parts of the latter substance are mixed intimately with five parts of pure carbonate of soda and five parts of chlorate of potash.

NOTICES OF PATENTS.

595. *Iron.* W. H. BUCKLAND, Barge Yard, Bucklersbury, London. Dated March 9, 1861.

This patent refers to the smelting or reduction of iron from the ore by the employment in the smelting furnace, crucible, or other receptacle, of a bath of melted cast-iron, into which the heated or semi-fused particles of ore may fall, and in consequence of being entirely surrounded by the fluid metal, become more quickly melted and reduced.

In the process of smelting iron in the ordinary blast furnace, a cistern is provided for the reception of the liquid iron, into which the metal runs freely, as produced, such arrangements having been devised as a means of maintaining a clear passage for the blast, and of permitting the ore not yet reduced to be surrounded by, and subject to, the uninterrupted action of the carbonic oxide gas generated in the hottest part of the furnace. According to the system now described, this potent action of the reducing gases cannot be exerted.

612. *Dyeing and Printing Textile Materials and Fabrics.* R. H. GRATRIX, Salford. Dated March 12, 1861. Not proceeded with.

This invention relates to the printing and dyeing of colours derived from aniline, nitro-benzol, naphthaline, cinchonine, and analogous substances. The inventor

[¹ Having given our readers the above information, we feel bound to add, by way of caution, that Her Majesty, "being willing to give encouragement to all arts and inventions which may be for the public good," has been graciously pleased to grant Royal Letters Patent to the inventor, his executors, administrators, and assigns, for the sole use, benefit, and advantage of the above invention. The Patentee, however, in consideration of a small sum, grants a licence for its use, and the apparatus required is ridiculously cheap.—*Ed. CHEMICAL NEWS.*]

produces a fast dye by passing cloth prepared with stannate of soda or other suitable mordant, through a thickened solution of tannin, and, after the ordinary dyeing, subjecting it to the fixing action of steam. After washing out the gummy matters, and drying, the material may then be dyed with any of the colours specified above. Or cloth or yarn, prepared as directed, may be passed through an acid or other solution of tannin, mixed with the colour intended to be used. Also, the mixed fabrics of cotton and worsted may be dyed by a more simple process than that commonly employed by passing the cloth through soap after the preparation of shumach or other such agent.

627. *Method of Fixing Colours in connexion with the Printing of Woven Fabrics and Yarns.* R. C. PATTISON, Daldorh House, near Catrine, Ayrshire; and A. M. PATTISON, Glasgow. Dated March 14, 1861. Not proceeded with.

For the purpose of fixing certain colours derived from tar products upon yarn and woven fabrics, the inventors employ tannin, in combination with an alkaline earth, in the process of printing.

The improvements suggested in this and the preceding specification are very similar. It is probable that the prior employment of materials containing tannin has operated in these instances adversely to the claim of novelty.

682. *Fixing Colouring Matters.* J. S. MILLER and T. P. MILLER, Springfield Works, Dalmarnock, North Britain. Dated March 18, 1861.

With the object of rendering more permanent such dyes as are procured from aniline and similar bases, the patentees entirely immerse the fabric in a solution of "the acetate of galls,"—i.e., tannin of nut galls dissolved with the addition of acetic acid. The material is then withdrawn and dried. In this condition it is ready for printing upon with a thickened colour of the following nature:—The aniline dye or other colouring matter obtained from similar sources is added to a solution of "tartro-acetate of stannate of soda or potash" in quantity sufficient to produce the desired shade of colour on the goods to be printed or dyed, and the mixture thickened by the addition either of gum, starch, dextrin, or other suitable farinaceous substances, employed in such proportion as will communicate to the colouring matter the requisite degree of consistence for printing on the fabric; or, in the case of dyeing by immersion, this last ingredient is altogether omitted. As the best means of fixing the colour, the printed goods are finally submitted to the action of steam in the ordinary way. For the preparation of the tin mordant specified above, the stannate of soda or potash is neutralised with tartaric acid and then slightly acidulated with acetic acid; or, instead of this combination, citric acid may take the place of acetic, or any other double salt of an alkaline stannate, with the potash or soda salt of other acids, may be substituted for those already described.

It is interesting to remark the close analogy, or even identity, between this specification and one of earlier date, No. 612, which was not proceeded with. In both processes stannate of soda and tannin are employed in combination with a free acid and a thickening agent.

693. *Producing Combinations of Certain Colours on Cotton Fabrics.* T. BROOKS, Sunnyside, near Rawtenstall. Dated March 20, 1861.

For the simultaneous production of aniline and madder colours in dyeing cotton goods, the inventor applies at once the mordants for these colours respectively, thereby rendering the fabric capable of taking up the various tints, or any combination of them, in the subsequent process of dyeing.

701. *Dyeing and Printing Textile Materials and Fabrics.* N. LLOYD and J. G. DALE, Church, near Accrington. Dated March 20, 1861.

As an improved method of fixing upon cotton and linen fabrics the several colours of the aniline class, described under the names of mauve, Magenta, roseine, &c., the patentees mix with any one of these tannin, and a thickening agent, such as gum, senegal, or other suitable mucilaginous material. The goods are printed with the above, then submitted to the steaming process, and finally passed through a boiling solution of tartarised antimony.

According to the terms of this specification the materials employed are the same as those just now described in Nos. 612 and 682, with the substitution, however, of antimony for tin in the mordant.

615. *Treating or Preparing Textile Materials and Fabrics.* A. PEEK, Manchester. Dated March 13, 1861.

In this invention it is the object of the patentee to increase the density of substance, and to improve the finished appearance of cotton and other vegetable textile fabrics and materials. In operating upon yarns or fabrics the first operation is preparatory, and consists in the removal of all gummy and greasy impurities, by submitting them to the ordinary process of "bucking," or washing. After such preliminary cleansing they are passed through a solution of silicate of soda or potash, employed alone, or in combination with a fatty or resinous soap. The yarns or fabrics thus prepared are dried by artificial heat or otherwise, and then aged or exposed to the atmosphere for as long a time as possible. In order now to fix the silica in the materials they are submitted to the action of any soluble salt, by surface padding or otherwise, which is capable of decomposing the alkaline silicate, and also the soap, when such has been employed, and by being rendered insoluble in this manner is precipitated within the substance of, or becomes incorporated with, the fibrous materials, yarns, or fabrics.

The impregnation of cotton and other fabrics, with the silicates of the alkalies and other compounds derived from the same, has frequently been practised for the purpose of rendering such materials less sensitive to the action of fire. These efforts have, however, been generally abandoned on account of the harshness and impoverished appearance of the fabric so treated, and with the exception of the method of preparation with soap and alum, applied to woollen material, no advantage beyond the single consideration to the manufacturer of rendering the goods more weighty seems likely to result from the mode of treatment here proposed.

619. *Silvering Glass, &c.* J. CUMBO, Great Portland Street, London. Dated March 13, 1861.

For the purpose of depositing a bright film of metallic silver upon glass and other services, the inventor employs ammonio-nitrate of silver, to which he adds a solution of Rochelle salt (tartrate of potash and soda). The silver is deposited by the action of this reducing agent at the ordinary temperature of the air, no external aid being required for the purpose of facilitating the production of the metallic film. The thin layer of silver so formed may be backed and strengthened by an electro-deposit of copper, or other cheap metal. This method of operating is also useful for the coating of small objects prior to electrotyping, which, being non-conductors of electricity, require to have a superficial conducting layer imparted to them. By commencing with a plate of glass having polished and dull surfaces, an ornamental device may be executed.

This process of depositing bright metallic silver upon glass was experimentally illustrated by Professor Faraday at one of his Friday evening lectures at the Royal Institution some years since. The brilliant lustre of the truly "silvered" surfaces was much admired.

Grants of Provisional Protection for Six Months.

2164. Hippolyte Lecaudey, Wellington Street, Strand, London, "Improved apparatus for succouring persons interred before life is extinct."—A communication from Raymond Malerille, Bordeaux, France.—Petition recorded August 30, 1861.

2323. George White, Pancras Lane, London, "Improvements in apparatus for filtering or purifying water or other liquids." A communication from Mr. Jean Antoine Victor Burg, Paris.—Petition recorded September 18, 1861.

2382. Thomas Davey, Tucking Mill, Camborne, Cornwall, "Improvements in the manufacture of safety fuses, parts of which are applicable to the manufacture of pipes and tubes of lead, and other soft metal, gutta-percha, caoutchouc, bitumen, and earthenware."—Petition recorded September 24, 1861.

2460. Edgar Breffit, King William Street, London, "Improvements in machinery employed in cutting hollow and solid corks."—Petitions recorded October 2, 1861.

2469. Robert John Ellershaw, Leeds, Yorkshire, "An improved machine for expressing oil."—Petition recorded October 3, 1861.

2482. Thomas Goulston Ghieslin, Hatton Garden, London, "Improvements in the treatment or preparation of certain foreign plants or vegetable substances, and of the application of the same to various useful purposes, for which horn, shell, whalebone, indurated leather, fish skin, ivory, bone, hard wood, and compounds of india-rubber or gutta-percha, have hitherto been employed."—Petition recorded October 4, 1861.

2515. Isham Baggs, Green Terrace, and James Thomas Parkes, Almorah Terrace, Middlesex, "Certain improvements in the manufacture and treatment of india-rubber and vulcanite as applied to various purposes."—Petitions recorded October 9, 1861.

2586. Charles de Groot, Brussels, Belgium, "An improved instrument for corking bottles and other vessels."

CORRESPONDENCE.*Economising the Waste Fumes from Vitriol Chambers.*

To the Editor of the CHEMICAL NEWS.

SIR,—In last week's Number there is a short account of a patent (514) for economising the waste fumes from vitriol chambers. A similar idea occurred to me three years ago. I found that although sulphuric acid does not dissolve metallic copper alone, it will do so if nitrous fumes are passed through it; I have made sulphate of copper in this way. The reason why the process was not largely carried out was, that the dilute acid only dissolves very little nitrous gas; strong acid dissolves large quantities;

but if the copper be placed in strong acid, and red fumes passed through the mixture, sulphate is formed, but in very small white-looking crystals, which are difficult to free from excess of acid economically.

The idea occurred to me then to treat pyrites containing both copper and iron, after burning, with vitriol and red fumes, and so to obtain a solution of sulphate of iron and of copper, by distilling gas liquor so as to pass the crude ammonia into the mixture; sulphate of ammonia and ammonio sulphate of copper remain, and the peroxide of iron precipitated may be re-dissolved in waste spirits of salts, to form a cheap persalt of iron for black, &c. dyeing. The mixed solutions I proposed to mix with copper scales (oxide) and evaporate to dryness, and heat in a retort to recover the ammonia, and leave pure sulphate of copper anhydrous. But the last operation has always failed from various causes already detailed; although ammonia is at first evolved, and sulphate of copper formed, afterwards other reactions take place. Although the idea of thus economising waste nitrous fumes failed with me, I am not aware that anyone has a priority on the score of originality. I may also add that I proposed an arrangement for the operation, which was perfect in its action. I arranged a series of Woulfe's receivers; in the first was a saturated solution of nitrous gas in strong vitriol, on adding water to which gradually the gas was evolved, and passed through the second; the gas, now reduced to nitric acid, was passed through the third, fourth, &c., with the addition of sufficient air to reconvert it into red nitrous gas. In the last receiver, strong vitriol absorbed the gas for another operation, by reversing the arrangement. Of course the receivers between the two extremes were charged with dilute acid and copper.—I am, &c.

JOHN S. BLOCKEY.

Sheepecar Chemical Works, Leeds, Nov. 14.

MISCELLANEOUS.

SCIENTIFIC NOMENCLATURE.

In reply to C. W. M., whose letter on this subject we reprinted from the *Athenæum* in our 101st Number, C. M. Q. writes as follows to the same paper:—

Although agreeing in the main with the remarks of your correspondent "C. W. M." on scientific nomenclature, I must take exception to that part of his letter in which he attacks the chemical philosophers. He sets out with the dictum, "Science is not for the idler." He must forgive me if I add a rider to it,—"Chemical nomenclature is not for the superficial." It is singular that he should find such fault with the only science amongst those which he aptly terms sciences of observation which possesses a perfectly intelligible and logical nomenclature. Chemical nomenclature, as founded by the immortal Lavoisier, is governed by a fixed principle, which ordains that every name shall express the composition of the substance for which it stands. An adept in chemical science knows at once the exact chemical composition of any body from the formation and termination of the name given to it. The word "methylethylsmylophenylammonium," which appears so unintelligible to "C. W. M.," is as easily remembered and understood by a chemist as "light blue, ruled, foolscap paper" would be by an ordinary individual. In this, chemical nomenclature stands in favourable contrast to that adopted by botanists. Such cacophonous epithets as "*Bogglesia Wigginsii*" simply afford the information that the plant so designated was discovered by the illustrious but mythical personages Boggles and Wiggins, without giving the smallest clue to its properties or character; but the term "Bichloride of rubidethyl," although just as imaginary, is the name of a substance, of certain composition, which may or may not be discovered some day. As to the synonyms possessed by a very few

chemical substances, it is the manufacturers and workmen who are the perpetrators of errors. Mere vendors cannot be posted up in the known composition of their wares. They are asked for spirits of salt, and they sell it. Ask them for hydrochloric acid, and they stare at you. As chemical science advances, names must necessarily change; but if "C. W. M." will examine the standard chemical works of the last twenty or thirty years, he will find but few alterations. The principal changes in this way are additions and not substitutions. When a new element or radical is discovered, a name is given to it descriptive either of its source or of some salient property. For instance, Bunsen has lately discovered two new metals, cesium and rubidium, by means of spectral analysis. Their names have been given to them from their forming blueish (*cesius*) and ruby lines in the spectrum. "C. W. M." is mistaken in saying that organic chemists call sulphates thionates. Sulphur compounds of the thionic series are *inorganic* substances, and are quite distinct in their composition from sulphates. Chlorhydric acid is simply the French form of hydrochloric acid; the difference in the two words being euphonic, and not theoretical, as in the long-abandoned name—muriatic acid. As to "hydrachlora," I fear it is only the invention of an enthusiast with a theory and nomenclature of his own. The proposed substitution for the ammonium compound must, I fancy, come into the same category; but, not having seen the article mentioned by "C. W. M.," it would be wrong to speak positively, "C. W. M." deserves the thanks of all scientific men for having stirred up the subject; and I trust it will be the means of calling forth many more remarks from abler pens than mine.

In conclusion, I beg to assure "C. W. M." that I make these explanations with perfect good humour, and only hope that he will be induced thereby to study chemical nomenclature a little more closely. He will soon see the beauty and intelligibility of such apparently absurd words as "ethylomethylpropylamine," and a host of others.

THE LIME LIGHT AT THE SOUTH FORELAND.

Five-and-thirty years ago Lieut. Drummond brought into notice the oxyhydrogen light, and applied it to a practical purpose. Having been appointed to conduct the Ordnance survey in Scotland and Ireland, he used this light in the focus of a parabolic reflector on lofty eminences, where the stations were usually placed, as it was of the greatest importance in those operations to have certain and determinate signals, which could be seen, under any circumstances as to weather, at great distances. Thus he succeeded in connecting the shores of England and Ireland, near Holyhead, a distance of 65 miles, and afterwards, in Scotland, the summit of Ben Lomond with that of Knock Laid, no less than 95 miles apart. It did not escape the comprehensive mind of Drummond to perceive that such a light, if capable of practical application, would be invaluable for lighthouse purposes. With the means he devised, however, he failed to obtain anything approaching practical command over the continuity of the light; and as a light that is liable to go out is inadmissible for lighthouse purposes, it is not surprising that it was condemned.

Since Drummond's time, until quite recently, the oxyhydrogen, or lime light, has been used only for the purposes of the microscope, or to produce scenic effects; not that the value of a light of such power and intensity has been lost sight of, but because all attempts to render it practically available in a commercial sense had failed.

The impossibility of turning it to a useful purpose seems to have so taken possession of the public mind, scientific as well as general, that although within the last two or three years, exhibition after exhibition, varying in duration from hours to months, have given the most incontestable proofs that with Bartable's apparatus the lime light can be burned as easily and certainly as a wax candle, yet, with a single but notable exception, not one eminent man of science has been found who has not scouted the idea of its practical utility. Upon almost every occasion of late, when our men of science have condescended to mention the lime light, it has been condemned by them as impracticable, and the idea of its applicability to any useful purposes contemptuously dismissed; whilst the assumption that it can be used for ordinary domestic purposes has met with most positive contradiction, interspersed, upon one or two occasions, with assertions as to the available sources and expense of oxygen gas, which, although valueless in themselves, are useful as indicating the amount and accuracy of information upon the subject possessed by some of those who have pronounced the severest condemnations of it. It has been the fashion in scientific circles to condemn the lime light, and there are few amongst those who have not compromised themselves more or less by decrying it; and experience will have taught us that from such we can expect but a tardy recognition of even a fact that is subversive of a long cherished dogma. This prejudice, which has seriously impeded the general introduction of the lime light, is traceable to its usual source—want of accurate information on the subject; for although the means were at hand, not one of those who ridiculed the idea that the lime light had been brought to a state of perfection, rendering its practical application to illuminating purposes easy and certain, took any trouble to make such an investigation as to the alleged fact as could justify the expression of any opinion at all. The public at large took the view of the *savans*, whose opinions were readily adopted and disseminated by those who are interested in the continuance of the present methods of producing artificial light; whilst the verdict of gas engineers, scientific advisers to Gas Companies, and other vested interests, upon the lime light was such as a notorious poacher might expect at the hands of a jury composed of cock-pheasants.

In the mean time, however, whilst the learned condemn it, and capital fought shy of it, the light went on burning steadily—carefully watched, examined, and, in course of time, appreciated by one, at whose hands truth never suffers, imposture is never spared, and whose opinions are ever formed for himself by patient and careful investigation, and not expressed until all doubt has been removed. Without having been made aware of the exact conclusions arrived at by this investigation, it must be supposed to have been favourable, as it led to a decision on the part of the Trinity Board to give the light a fair trial in a first order lighthouse, for which its peculiar qualities are pre-eminently fitted. To this end a contract was entered into with the Universal Lime Light Company by the Elder Brethren for the exhibition of the light in the South Foreland Lighthouse for three months, and upon its success will, in all probability, depend its extensive adoption for the purposes of coast lighting. The light was introduced on the 26th of August, and has continued to burn steadily and brilliantly every night since its substitution for the oil light. Indeed, after the report of Mr. Page, the engineer of Westminster bridge, upon the success of the lime light which for two months illuminated the finished part of that structure, no doubt can exist as to the facility with which it can be maintained, for no case of failure occurred there in maintaining regularly eighteen lights in nine different lamps, where the operation of making the gases had to be conducted upon temporary platforms, suspended between wind and water, and the whole arrangements necessarily of an incomplete and

temporary character, added very largely to the ordinary risk of a failure occurring. The lamp at the South Foreland is fitted with eight burners, to meet the requirements of the Fresnel apparatus, which is composed of eight panels: only six out of the eight burners, however, are required, as the two panels towards the land are darkened. The manipulation of the lamp is perfectly simple, not necessitating an amount of intelligence greater than is required in the case of an ordinary Argand lamp. When the time for lighting comes the lime wicks are inserted, the clock which moves them wound up, and the gases turned on, and no further attention is required until the hour arrives for putting out the light, when the gases are turned off, and the clock is stopped; the lime wicks are then removed, and nothing further remains to be done. The brilliancy of the light has not escaped the notice of our friends on the other side of the Channel, many of whom have been over to visit it. It is but fair to state that the present apparatus in which the lamp is exhibited is not calculated to give the maximum effect, having been especially adjusted for the usual Argand oil lamp, which differs from the lime light in the essential particular of focal distance, which is measured from the centre of the former, but from the surface of the latter; the lime light, therefore, although of the same diameter as the oil flame, is too near the lenses by half its diameter—in this case by $1\frac{1}{2}$ inches. It is to be hoped that this light will be tried both in a French apparatus, specially adjusted, and in the focus of a paraboloid, for it appears to possess every element, rendering it by far the best light for coast purposes ever introduced.

Amongst other attributes of the lime light is another of the very last importance. It is not affected by wind, even though unprotected by glass. At Liverpool, where the lime light was exhibited for two months upon the landing stage where the Birkenhead ferry boats ply, this property was most severely tested. One night a gale of wind came on, and increased in violence until the glasses of the lanterns were dashed in, and the light was exposed to its full power. No apparent effect was produced upon them, for they continued to burn as steadily and brightly as before. It has happened not so unfrequently as might be imagined, that the glass of our lighthouses has been broken, in violent gales, and the light blown out.

Professorship of Chemistry at Cambridge University.—This Professorship having become vacant by the death of the Rev. James Cumming, the election of a new Professor will take place on Friday, the 6th day of December next. The electors to the Professorship are the persons whose names are on the electoral roll of the University. The Vice-Chancellor and the proctors will receive the votes of the electors from eleven o'clock in the morning till one o'clock, when the Vice-Chancellor will declare the election.

ANSWERS TO CORRESPONDENTS.

* * All Editorial Communications are to be addressed to the EDITOR; and Advertisements and Business Communications to the PUBLISHER at the Office, 1, Wine Office Court, Fleet Street, London, E.C.

* * In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

H. A. Simcol.—The minimum thermometer can be procured at Mr. Cassell's, Hatton Garden, London.

A would-be Member.—Write to the Secretary, Burlington House, Piccadilly, who will forward you the necessary information and blank forms to be filled up.

E. Ballard.—Received with thanks. In our next.

THE CHEMICAL NEWS.

VOL. IV. No. 104.—November 30, 1861.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Suggestions for a New System of Chemical Nomenclature, with reference more particularly to Organic Substances, by JOHN A. R. NEWLANDS, F.C.S.

CERTAIN letters, or syllables, are employed to denote the various quantities of each constituent in the substance named, and by uniting these the names are produced.

The accompanying list of numerals, which may be learned without much difficulty, is adapted for this purpose, though it, no doubt, admits of great improvement. Names constructed on these principles can be converted into formulæ, and formulæ into names, with the greatest ease, the one being an exact counterpart or reflex of the other. The names thus created may be either used *per se* or in conjunction with those at present existing. Thus, caprylic acid, $C_8H_{16}O_2$, may be either called meddatic acid, or medda-caprylic acid; and milk-sugar, $C_{12}H_{24}O_{12}$, may be named sepsatone, or sepsatic sugar, or sepsa sugar.

The numerals chosen for carbon are the consonants, simple and compound; thus, *b* signifies one of carbon; *d*, two of carbon; *f*, three; *g*, four; and so on in alphabetical order. The letter *c* is not employed, as its sound is always identical either with that of *k* or of *s*. *Q* and *x* are omitted for equally good reasons.

The numerals for hydrogen consist of a vowel followed by a consonant: thus, *ab* signifies one of hydrogen; *ad*, two; *af*, three; *ag*, four, &c.

Those for oxygen are simply the reverse of the preceding: thus, *ba* signifies one of oxygen; *da*, two; *fa*, three; *ga*, four, &c.

Lastly, the name is completed by a termination indicating its chemical properties: thus, acids may be made to end in *-ic*; bases, in *-ine*; neutral bodies, in *-one*; and hydrocarbons, in *-yl*.

The name of the group to which a substance belongs may also be frequently appended with advantage, such as *sugar*, *alcohol*, *aldehyde*, &c.

When two vowels come together, the letter *t* may be inserted to preserve euphony.

The following examples may serve to illustrate the method of nomenclature:—

1. Give the name of starch, $C_{12}H_{20}O_{10}$. Now, C_{12} is *s*; H_{20} , *ek*; and O_{10} , *pa*; the name is, therefore, *sekpato-ne*, or *sekpatic starch*.

2. Name, phenyl, C_6H_5 . C_6 is *k*; and H_5 , *ah*; the name is, therefore, *kahyl*, the base, phenylamine, $N(C_6H_5)_2$, being called *kahylamine*.

3. Name, ethylic-alcohol, C_2H_5O . C_2 is *d*; H_5 , *ah*; and *O*, *ba*. The name thus formed is *dakba*, or *dakbatic-alcohol*.

4. Give the formula of *mahban-one*. Here, *m* is C_8 ; *ah*, H_3 ; *ba*, *O*; and *n*, *N*. The formula, therefore, is, C_8H_3NO , or blue indigo.

5. What is the formula of *lakdatic acid*? *l* is C_7 ; *ah*, H_3 ; and *da*, O_2 . The formula, then, is, $C_7H_3O_2$, or benzoic acid.

6. Give the formula of *zehfan-ine*. *z* is C_{17} ; *eh*, H_{10} ; *fa*, O_3 ; and *N*, *n*; giving the formula, $C_{17}H_{10}NO_3$, or morphine.

Isomeric substances are distinguished by making a difference in their termination, thus:—

Allylic glycerin, $C_3H_5O_3$, "*fakfatic*" glycerin, or *fakfaterin*. Lactic acid, $C_3H_5O_3$, "*fakfatic*" acid.

The amount of nitrogen in a substance is indicated by the letter *n*, with or without a vowel, placed immediately before the end of the name: thus, *n* is *N*; *na*, N_2 ; *ne*, N_3 ; *ni*, N_4 , &c.

In like manner phosphorus may be represented by *p*, *pa*, *pe*, *pi*, &c.; arsenic by *r*, *ra*, *re*, *ri*, &c.; sulphur, by *s*, *sa*, *se*, *si*, &c. The same plan may be extended to other elements.

If one of these syllables be followed by a vowel, the letter *m* is inserted instead of *t*, in order to distinguish between substances containing *N* and those containing NO_2 .

Nomenclature of Substitution Products.

These may be named as at present, thus benzoic, nitrobenzoic, and binitrobenzoic acids may be termed *lakdatic*, *nitrolakdatic*, and *binitrolakdatic* acids, respectively; or a syllable may be introduced expressing the number of equivalents of hyponitric acid, chlorine, bromine, iodine, &c., which have replaced hydrogen in the normal substance: thus,—

Benzoic acid, $C_7H_5O_2$, *lakdatic acid*
Nitrobenzoic acid, $C_7(H_4NO_2)O_2$, *lakdanatic acid*
Binitrobenzoic acid, $C_7(H_2NO_2)_2O_2$, *lakdanetic acid*

Different quantities of NO_2 being represented by the syllables, *nat*, *net*, *nit*, *not*, and *nut*; of chlorine, by *cat*, *cel*, &c.; of bromine, by *bat*, *bet*, *bit*, &c.; and of iodine, by *dat*, *det*, *dit*, &c. Thus, in the case of acetic acid we have,—

Acetic acid, $C_2H_4O_2$, = *dagdatic acid*
Monochloroacetic acid, $C_2(H_3Cl)O_2$, = *dagdacatic acid*
Trichloroacetic acid, $C_2(HCl_3)O_2$, = *dagdacitic acid*
Monobromoacetic acid, $C_2(H_3Br)O_2$, = *dagdabatic acid*
Dibromoacetic acid, $C_2(H_2Br_2)O_2$, = *dagdabetic acid*
Iodoacetic acid, $C_2(H_3I)O_2$, = *dagdadatic acid*
Diiodoacetic acid, $C_2(H_2I_2)O_2$, = *dagdadetic acid*

As every change in composition is accompanied by a corresponding change in name, all the various modes of arranging bodies, such as homologous and isologous series, different degrees of oxidation, &c., have characteristic terms allotted to them.

Names deduced from empirical or rational formulæ may be distinguished as empirical or rational names. Thus, the rational name for aniline, $N(C_6H_5)_2$, is, as we have already seen, *kahylamine*; the empirical name, deduced from the formula C_8H_7N , is *kalnine*. Those of similar bodies, containing phosphorus or arsenic, in the place of nitrogen, would be,—

C_6H_7P , *kalpine*, and
 C_6H_7As , *kalrine*.

List of Numerals.

This list furnishes the names of organic compounds up to those containing 34 equivalents of C and 68 of H or O.

The numerals for O are merely the reverse of those for H; it is, therefore, only necessary to learn the latter.

Researches on the Relations existing between Atomic Weights, by M. J. S. STAS, Member of the Royal Academy of Belgium.

(Continued from page 272.)

Determination of the Proportional Relation between Silver and Chloride of Sodium.—I have made ten determinations of the proportional relation between silver and chloride of sodium. To effect this I made use of chloride of sodium prepared by six different processes. I will describe each of them briefly.

I. Chloride of Sodium from Carbonate of Soda.—Commercial bicarbonate of soda was heated to dull redness in a silver dish, to render insoluble the iron which this body always contains. The residue, after cooling, was dissolved in pure cold water, and the solution evaporated to a pellicle in a platinum dish, and then allowed to crystallise. This was repeated ten successive times.

The carbonate was transformed into chloride in the same platinum vessel by passing a current of pure hydrochloric acid through the solution. The resulting salt was dried, heated to dull redness, and then taken up with cold water. The solution was decanted after standing twenty-four hours to separate the silica which was deposited, and then evaporated again. The chloride of sodium, which was perfectly white, was mixed with a tenth of its weight of pure chloride of ammonium containing chloroplatinate of ammonia, and then treated as I have explained above in the case of chloride of potassium obtained from nitrate of potash.

Chloride of sodium thus prepared is perfectly colourless and slightly hygrometric, a property which is not possessed by chloride of potassium. Its specific gravity differs according to whether it has been slowly or rapidly cooled after fusion. I have found it comprise between 2.125 and 2.150. When dissolved in cold water it produces a neutral and perfectly limpid solution.

Nos. I. and II. show the results furnished by two

specimens of chloride produced from two distinct samples of carbonate. The silver used in No. II. was prepared by M. Liebig.

II.—Chloride of Sodium from Colourless Rock Salt.—Some perfectly colourless rock salt free from iron, manganese, and sulphate, but still containing traces of magnesium and calcium, was submitted in a platinum dish to six crystallisations from a hot solution. As it was possible that the boiling mother liquid might contain potassium, this was always thrown away. The perfectly white salt was pulverised and exhausted with alcohol at 96 per cent., and then digested with alcohol at 65, containing bichloride of platinum. The clear alcoholic solution was separated and replaced by a fresh quantity of alcohol at 70, still containing bichloride of platinum, until about one-third of the salt was dissolved. These solutions were mixed together.

The residuary saline mass was treated with a fresh quantity of alcohol at 70, containing bichloride of platinum, until about one-third of the salt employed was left undissolved. The solutions obtained by this second treatment were then mixed together. The first and the second solution each represent, therefore, a third of the total weight of the salt experimented upon. The two solutions were separately precipitated by absolutely pure sal-ammoniac. After standing sufficiently long, they were decanted and evaporated to dryness in a platinum retort. The salt was mixed with pure sal-ammoniac and chloroplatinate of ammonia, and treated as I have explained in the case of chloride of potassium from nitre.

No. III. shows the result furnished by some of the first third of the salt, and Nos. IV. and V. the results obtained by some of the second third. The extraordinary concordance of these results proves the identity of the two chlorides, and demonstrates also to what accuracy it is possible to arrive by the wet way.

III.—Chloride of Sodium from Sulphate of Soda.—Sulphate of soda freed from all foreign metals by the ebullition of its solution with a slight excess of sulphide of sodium and carbonate of soda, was submitted to ten successive crystallisations. The salt thus obtained was dried in a platinum dish and mixed with twice its weight of chloride of ammonium prepared by the direct action of ammonia and pure hydrochloric acid. The mixture was heated to dull redness. The residue, mixed again with its own weight of pure sal-ammoniac, was heated to redness a second time. All the sulphate is thus converted into marine salt contaminated with traces of platinum and silica. It was fused with a small quantity of pure sal-ammoniac and chloroplatinate of ammonia, and treated as previously explained in the case of chloride of potassium from nitre.

No. VI. shows the result furnished by this salt.

IV. Chloride of Sodium from Tartrate of Soda.—Pure carbonate of soda was neutralised by tartaric acid prepared by decomposing tartrate of lead with hydrosulphuric acid.

The tartrate, crystallised a great many times, was dried and boiled several successive times with alcohol at 96, and then transformed into chloride by the means which I employed in the preparation of chloride of potassium from pure cream of tartar.

The result obtained is shown at No. VII.

V. Chloride of Sodium from Nitrate of Soda.—With this object I have prepared pure nitrate of soda from Chili saltpetre, from which I have eliminated the foreign metals by a mixture of sulphide of sodium and carbonate of soda, and which I have then crystallised at least ten successive times from pure water. This nitrate

was converted into pure chloride by the means employed to convert saltpetre into chloride of potassium.

No. VIII. shows the result obtained by this chloride.

VII. Chloride of Sodium from Chloro-platinate of Soda.—The chloride of sodium from rock salt, purified with bichloride of platinum and alcohol, and of which the results are given in Nos. III., IV., and V., was mixed with three times its weight of bichloride of platinum. The mixture was dissolved in pure water, and the solution evaporated to dryness. The residue taken up by a small quantity of water, at once completely dissolved in it. This solution, evaporated to a pellicle, was allowed to crystallise; the mother liquor was decanted. The crystals of a pure golden yellow colour were taken up by the smallest possible quantity of boiling water, and furnished, upon cooling, a fresh crystallisation of chloroplatinate of soda. I have in this manner effected the solution and crystallisation of chloroplatinate of soda six successive times. At this point I removed a certain quantity, and continued the solutions and crystallisations six times more.

The two chloroplatinates thus prepared were of a pure golden yellow. After having dissolved them in water, I decomposed them separately with pure chloride of ammonium, and evaporated the solution to dryness in a platinum dish. The resulting chlorides were then treated as I have above explained in the case of chloride of potassium from nitre.

In submitting the chloroplatinate of soda to so great a number of crystallisations, my object was to concentrate in the mother liquors the chloroplatinates more soluble than that of soda, and in the chloroplatinate of sodium the chloroplatinates less soluble than this; chloroplati-

nate of potassium, for instance, if by any means the salt employed in the preparation of the double salt could contain traces of a potassium compound.

I commenced the operation with about three hundred grammes of chloroplatinate of soda, and at the end of the operation I had separated above two-thirds of the compound with the mother liquors.

No. IX. shows the result obtained by means of the salt prepared from the chloroplatinate, which was crystallised six times; and No. X. that of the salt crystallised twelve times. The almost absolute identity of the two results prove in the clearest manner that the salt employed contains no chloride capable of producing a chloroplatinate less soluble than that of soda. This identity proves, moreover, that the double salt contains no chloride having a higher equivalent than that of chloride of sodium itself.

All the specimens, indiscriminately, of chloride of sodium experimented upon were colourless, and dissolved in water, producing a neutral and absolutely limpid liquid. I happened to preserve for a month in a stoppered glass vessel a solution of this compound, without perceiving the slightest trace of any deposit. I am, therefore, thoroughly convinced that it is impossible by the means at present at our disposal to prepare this chloride in a state of greater purity.

As the purest marine salt is slightly hygrometric, when I weighed it, I always heated it nearly to redness in a closed platinum crucible, and immediately introduced it into a tube closed at one end and furnished with a glass stopper ground in and pierced with a small hole. During cooling, this tube was placed under a bell-jar with sulphuric acid.

Parts of Chloride of Sodium.

(To be continued.)

On the Adulteration of Butter with Animal Fats, by EDWARD BALLARD, M.D. Lond., M.R.C.P., Medical Officer of Health for Islington, and Parochial Analyst under the Adulteration of Food Act.

As the ether test for foreign fats in butter, described by Mr. Horsley in a recent Number of the CHEMICAL NEWS, is somewhat an expensive one, and, on this account the less likely to come into much practical use, I am induced to send for your readers a description of some other tests cheaper and more readily applied.

The most frequent adulterating fat by far is that of beef. We may call it beef "dripping" if we will, dripping being the form in which the fat I refer to is

best known. That such is the case may be seen by any one who will collect at 65° the residue of solution by ether and melt it in a watch-glass. It will, on cooling, be seen to possess the physical characters of beef dripping, with the exception of the odour and taste, both of which are wanting. These characters are, a dull, yellowish colour, granular texture, but less so than mutton dripping, melting slowly on the tongue, with a granular feel when the tongue is moved upon it. Its consistence is firm, and when the mass is broken by a spatula the granulations do not separate like those of mutton, and its consistence is more waxy. Mutton dripping is white.

The simple distinguishing character between pure butter and butter adulterated with beef dripping may

be noticed in the following particulars:—Its colour, consistence, odour, the appearance on washing with hot water, the occurrences on drying on blotting-paper, the physical characters when dried, and the results on pressure of the dried mass. To render these observations more precise in statement, I will give them in parallel columns, the adulteration of the butter for this purpose being supposed to be in equal proportions of butter and beef dripping.

Butter, newly churned and free from salt.

Colour.—Bright yellow—uniform.

Consistence.—Firm at 54°.

Odour.—Strongly butyraceous.

Appearance on washing, in a glass half-a-pint beaker, one oz. with boiling water.—A melted layer occurs on the surface, consisting, as viewed at the side of the beaker, of minute drops, which, lying closely together, give a finely cellular aspect to the layer. When cool the cake is a soft solid, fluctuating on agitation of the glass, or, at any rate, yielding readily when the glass is tilted. The water below is very opaque with milkiness. The cake is yellow.

On Transference to Blotting-paper.—The mass is wet, and the wet runs away slowly.

The blotting-paper acquires a marked yellow, greasy stain, which runs extensively over it. On transferring the butter to a second fold of paper, this stain is again imparted.

Physical Characters of Dried Butter.—Colour, bright yellow—odour, butyraceous—breaks under pressure of the spatula at 54° into fine mealiness—taste, butyraceous, not melting on tongue so smoothly as unwashed butter, but still quickly, and with little sense of granulation.

Butter Adulterated with Dripping.

Paler (paleness increases with the proportion of dripping)—often marbled yellow and white.

Firmer (increasing with proportion of dripping).

Butyraceous odour lessened (but still present even in large amounts of adulteration).

The melted layer consists of much larger drops, and the cellular appearance, therefore larger. On cooling, the cake is firmer, paler in colour, sometimes marbled, does not yield at all or much less readily to tilting of the beaker. The water below is less opaque with milkiness, (and often deposits dirt from the salt used in preparation).

The mass is almost dry on removal from water, and the remaining water rapidly runs away into the paper.

The stain to first blotting-paper is less marked, and that to second also. Both are of a less deep tint.

Colour less yellow—odour, that of dripping, but more or less butyraceous (this varying with the relative proportions of the two)—has a coarsely granular appearance in mass, and on gentle pressure with a spatula at 54° breaks down into independent granules very readily, these being the size of fine pearl sago and globular in shape—taste of the dripping distinctly perceptible (in low degrees of adulteration this is less marked)

Pressure of a little heap the size of a pea firmly and quickly by a spatula between a fold of blotting-paper gives an irregular, ill-defined, greasy stain, not very marked.

These tests are such as may be readily applied by a wholesale or retail purchaser. These are by no means all the signs easily applicable for distinguishing this form of adulteration. Should the present paper receive insertion and be acceptable to your readers, I shall be happy to furnish others which have resulted from my investigations on this subject. It is one especially interesting to me, since it is believed that at Belle Isle—a nest of nuisance factories in my parish—the material for the adulteration of butter is manufactured to a great extent for exportation. The "fresh" butters are those chiefly and to the greatest amount adulterated with this fat.

Parochial Laboratory, Islington, November 12.

[We shall be glad to receive further communications from this Correspondent.—ED. C. N.]

Researches on the Separation, by the Wet Way, of Gold or Platinum from Tin and Antimony. Reduction of Perchloride of Iron by Platinum, by MM. A. BÉCHAMP and C. SAINTPIERRE.

IT is not a matter of indifference as to which ferrous compound is made use of as a reducing agent. The sulphate and chloride reduce nitric acid of the metallic or organic nitrates, and gold from the chloride of gold, but they do not reduce nitro-benzole and analogous nitro-compounds, or bichloride of platinum. By substituting ferrous acetate for sulphate and chloride, all these compounds are reducible, and platinum especially is reduced to a metallic state.

Profiting by these indications, we propose to separate, by the wet way, gold and platinum from tin and antimony. We have previously proved that neither ferrous chloride nor acetate will reduce either chloride of antimony or bichloride of tin, even by boiling, and that qualitatively it is easy to precipitate gold and platinum by ferrous acetate in presence of these chlorides. The gold may even be precipitated, in the first instance, by protochloride of iron from a solution containing tin, antimony, and platinum, and the metal exactly estimated.

On our endeavour to estimate platinum which had been precipitated by acetate of protoxide of iron, we found this problem complicated by many difficulties which we first of all strove to overcome. The chief difficulty we met with was, that, though all the platinum was precipitated by acetate of iron, its weight was generally too low. We then reflected on the peculiar nature of platinum, and particularly on the fact that a body so difficult to attack might furnish a chloride irreducible by protochloride of iron. From this conjecture to the supposition that platinum might be a reducing agent there was but a step. In effect, platinum reduces perchloride of iron into protochloride, and is

—does not melt so smoothly or readily on the tongue, but for a long time a roughness remains upon it, increasing as it melts.

The stain is a circular, well-defined, oily spot, which soon becomes surrounded by a less greasy halo. (The perfection of this stain appears to vary with the quantity of the adulterant.)

itself dissolved in the liquid in the state of bichloride, according to the equation $\text{Pt} + 2 \text{Fe}_2\text{Cl}_3 = \text{PtCl}_2 + 4 \text{FeCl}$.

The weights of the reduced platinum were too low, because in freeing it by hydrochloric acid from the peroxide of iron precipitated with it a portion was redissolved, by virtue of an inverse reaction. This new and unexpected property of platinum we have established by the following experiments:—

1. Reduce 10 cubic centimètres of bichloride of platinum, containing 0.117 grammes of metal, by ferrous acetate. Next day add some perchloride of iron and a little hydrochloric acid, and after boiling two or three hours, all the platinum is redissolved.

2. Reduce in the same manner 5 centimètres of the same bichloride, containing 0.0585 grammes of platinum, and as soon as possible heat the precipitated metal with perchloride of iron. Ten minutes' boiling redissolves the whole.

3. Heat in a sand bath, with a solution of perchloride of iron acidulated with hydrochloric acid, 0.291 grammes of spongy platinum, prepared by the calcination of chloro-platinate of ammonia. Carefully add from time to time weak hydrochloric acid to maintain a constant volume. After eighteen or twenty hours' action between 80° and the boiling point of the mixture, all the platinum is dissolved.

4. 0.05 grammes of platinum black prepared by Liebig's process with hydrochloric acid, is not attacked after prolonged boiling with hydrochloric acid. Twelve hours boiling will completely dissolve it in perchloride of iron.

5. A platinum plate thoroughly cleaned with boiling hydrochloric and sulphuric acid, and then made red hot, weighed 3.294 grammes. Then it was heated in the same manner as indicated above with perchloride of iron. After twenty-one hours it was washed, heated, and weighed. Its weight was not more than 3.243 grammes, having lost 0.051 grammes. The platinum, then, is dissolved with difficulty in proportion as it is less divided and more dense.

The hydrochloric acid and perchloride we employed contained no free chlorine. That the dissolving of the platinum might not be attributed to the accidental presence of chlorine, we took care in each experiment, by means of red prussiate, that the perchloride of iron should be partially reduced into protochloride, forming Turnbull's blue. The perchloride was prepared by the process we published in 1859—the chlorination of a protochloride of iron solution by chlorine. This compound gives no precipitate, and not being coloured blue by red cyanide, the accidental presence of chlorine is then out of the question. Consequently, if protochloride of iron does not reduce bichloride of platinum, it is because platinum in this case is the more powerful reducing agent.

It would be interesting to study from the same point of view the metals partaking of the nature of platinum, palladium, iridium, &c. We propose to do this in continuation of the work which has been the subject of this memoir.—*Comptes-Rendus*.

On the Presence of Free Nitric Acid and Oxygenised Nitro-compounds in Atmospheric Air, by M. S. CLOEZ.

THE presence of free nitric acid and oxygenised nitro-compounds in atmospheric air has not been hitherto clearly and fully established. It is important for the

theory of nitrification that this apparently simple but really complicated question, confounded as it is with the question of ozone, should be experimentally resolved. To this end I have made the following observations:—

Ordinary air, collected by an aspirator at about a metre from the earth's surface, often makes the blue colour of wet litmus paper turn permanently red.

The tincture of blue-violet litmus, contained in a bulb-tube, through which air is passed, undergoes the same change. It has been proved that the red colour is persistent after heating the liquid to the boiling-point.

This phenomenon does not take place in all seasons indifferently, but it is frequent at the beginning and end of winter.

The nature of the acid producing this coloration is determined by passing the air into a solution of pure carbonate of potash, when a notable quantity of nitrate of potash will be found in the liquid, and generally traces of alkaline chloride, but no sulphate. The air must be filtered by passing through a pellet of asbestos.

Pure carbonate of lead substituted for carbonate of potash, and placed in a long glass tube, into which air passes, absorbs the acid vapours, forming nitrate of lead, soluble in cold water, and which is crystallisable.

Iodised starched paper has not been intentionally employed to detect the nitric acid of the air, yet this reagent is more sensitive to the action of nitrous compounds than litmus-paper; for it becomes coloured almost instantaneously in air, to which is added 0.00005 its volume of hyponitric acid, whilst litmus-paper, under these circumstances, would undergo no change.

The action of artificial nitrous air on solution of iodide of potassium produces, first, a saline compound, with a slight alkaline reaction, persisting in presence of iodine, but disappearing under the influence of an excess of nitrous air.

This singular phenomenon is similarly produced with air supposed to contain ozone. The phenomenon is explicable in both cases, by admitting the momentary formation of a small quantity of nitrite of potash, its reaction being, in fact, slightly alkaline. Whatever the true cause of the phenomenon, the inference is the same,—namely, that all the ozonometric observations made according to the process devised by M. Houzeau, are as inexact as all those previously made with Schœnbein's re-agent.

The recognised existence of free nitric acid in the atmosphere accounts for the presence of ammonia in certain specimens of rust, and the almost entire absence of it in others. It is very probable that the ammonia contained in the oxide of iron, formed in free air, is the result of the combination of nitrogen, proceeding from the reduction of nitric acid, with the hydrogen produced by the simultaneous decomposition of water. If this is the case, it is easy to understand that rust formed in humid air, freed from acid vapours, ought not to contain ammonia, like that formed in free air.

The formation of verdigris on unvarnished bells and bronze statues may be also, in a great measure, attributed to the free nitric acid of the air. An examination of green matter taken from a bell exposed to the inclemencies of the weather since 1793, has shown the presence of nitric acid.

In regard to agricultural science, the presence of nitrous compounds in the air is of the greatest importance: it accounts for the good effects of slight and superficial liming as well as marling; in short, it helps to explain the success of the agricultural practice of which M. Chevreul has recently given the theory and

set forth the advantages,—namely, the operation of *ecobuage* with combustion, originated by the Marquis of Turbilly, and carried out by him on a vast scale and with complete success.—*Comptes-Rendus*.

Rubidium and Cesium.

PROFESSOR BUNSEN announces that he has received a considerable quantity of a *lithioniferous mica*, containing more than three per cent. of cesium and rubidium, and, consequently, suitable for the preparation of these new bodies on the large scale. M. Seybel, the head of a large manufactory of chemical products at Liesing, near Vienna, has procured large quantities of lepidolite from Rozena, in Moravia, and of lithioniferous mica from Finnwale, in Bohemia, in order to extract from them *lithia*, *cesia*, and *rubidia*.

PHARMACY, TOXICOLOGY, &c.

On the Copper Test for Sugar, by JOHN HORSLEY.

A FEW weeks since the CHEMICAL NEWS contained a review of "Braithwaite's Retrospect," in which allusion was made to a new cupreous preparation, by Dr. Pavy, for the detection and estimation of sugar, which he recommended as being superior to either Barreswill's or Fehling's. In that respect I differ with him, having tried his method, and object to it on account of the excess of caustic potash it contains, having known instances where the copper was reduced *per se* on standing.

Like the Doctor, I have been so dissatisfied with the reduction by copper solutions as to direct my attention to other agents, till I found out that it was not so much the test itself as the mode of manipulation that required improvement, the copper test being delicate enough when well prepared and the saccharine fluid sufficiently pure. The ordinary method of procedure is, I believe, pretty much as described by Dr. Pavy,—viz., to boil and decolorise the cupreous liquor by the addition from time to time of the saccharine solution, it being generally supposed that the powers of the sugar are defunct at the moment the blue colour disappears, than which nothing is more fallacious, the sugar being then in excess, as may be proved by a further addition of the test and re-boiling. In fact, you may even make such an addition of the test as that, on boiling and filtering, the liquor shall pass through highly coloured and yet contain sugar, which will not cease to reduce copper till after two or three other boilings and filtrations have been made. The filtered liquid being permanently blue or bluish-green, and yielding no further red precipitate after several minutes' boiling, is the alone criterion of the exhaustion of the sugar, which is just the inverse of the present method. The filtered blue liquid may be again rendered available for other reductions by concentration or evaporation down to about the tone of the original copper solution used. The following is the formula by which I make the solution of copper:—Sulphate of copper, half-a-drachm; distilled water, three ounces. Dissolve by heat, then add, tartaric acid, half-a-drachm; and, when cool, caustic potash, one and a-half drachms; and, lastly, pure carbonate of potash, one and a-half drachms. An ounce of this liquor boiled with half-a-grain of grape sugar, dissolved in a little water, gave a scarlet red precipitate of one and a-half grains, every three parts representing one of sugar. The $\frac{1}{10}$ th part of a grain of sugar produces a decided precipitate.

Diabetic urine ought to be purified by precipitation with excess of sugar of lead, and any remaining lead thrown out by passing a stream of sulphide of hydrogen, the liquid filtered and evaporated to about half its bulk previous to applying the cupreous liquor; but if the quantity of lead salt be nicely adjusted, there will be no necessity for using the gas. High-coloured urine, supposed to contain sugar, requires, in addition to the precipitation by lead, to be decolorised by animal charcoal, and before using the test any lime which may have been acquired from the charcoal should be extracted by boiling the filtrate with a little carbonate of potash and filtering. Such urine will not afford, like true diabetic urine, a red precipitate, but a muddy, yellow one, if sugar exist at all, and the filtered liquid, instead of being blue, will be yellowish green.

Although it has been stated, on the authority of Brücké and others, that sugar obtains in ordinary or healthy urine, I have not been able to verify it by tests, owing probably to not having operated on a sufficiently large quantity. The only way of proving it, I presume, would be by carefully evaporating to an extract the purified urine and adopting the fermentation process.

Laboratory, Police Station, Cheltenham.

On the Properties of Sulphate of Aniline.¹

DR. TURNBULL, of Liverpool, read a Paper "On the Properties of Sulphate of Aniline"—a new remedy which he had used with success in the treatment of chorea, or St. Vitus's dance. He said that medical men had not acquired a knowledge of the properties of new remedies commensurate with the advances which had been made in other branches of medicine. The progress of organic chemistry had brought to light many new bodies worthy of investigation; and there could be little doubt that many of them would, if their properties were investigated, be found to prove remedies of utility. The artificial alkaloids were a numerous class, and from a resemblance in chemical constitution to the vegetable alkaloids, such as quinine, morphia, &c., it might reasonably be expected that some of them should have powerful and useful properties. He had made some trials of more than one of them, and especially of the sulphate of the artificial alkaloid aniline, which he had administered in cases of nervous disorder. He then proceeded to give an account of six cases of chorea which he had treated successfully with this new remedy. The first was a case of a girl, aged thirteen, who had involuntary twitching movements in all the limbs, and was for two months under the usual treatment, but without deriving the slightest benefit till the sulphate of aniline was given. She then recovered rapidly, and got quite well. The second was a case in which the left side was chiefly affected, and the recovery was perfect in twenty-one days. The third was a case in which the twitching movements were brought on by a fright, and the recovery took place in fourteen days. The fourth and fifth were cases of recovery from the ordinary form of the disease. The sixth was a case of unusual severity, with partial loss of power of the lower limbs and inability to speak. Rapid and perfect recovery was, however, effected in this case by means of the same remedy. He adverted to two other cases in which sul-

¹ Read before the British Association.

phate of aniline had been used with success by other medical men: and he expressed the conviction that it would be found by the profession to be a valuable new agent in the treatment of this class of nervous diseases. In regard to the physiological action, he stated that aniline appeared to act directly on the nervous system. The most remarkable effect, however, which it produced was a transient alteration in the colour of the skin and lips, which he attributed to oxidation of the aniline and the formation of a colouring matter in the blood. But this, it was observed, must be speedily eliminated from the system, as the natural colour was restored as soon as the remedy was laid aside.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, November 21, 1861.

Dr. A. W. HOFMANN, F.R.S., President, in the Chair.

Peter Macowen, B.A., Professor of Chemistry at Huddersfield College, was elected a Fellow.

Dr. THUDICHUM read a paper "*On Leucic Acid.*" He commenced by stating that the present paper contained an account of one of a series of researches on the products of decomposition of albuminous substances, either by reagents, or within the system. It had been known for some time that fibrin, under the action of hydrochloric acid, produced two bodies—leucine and tyrosine, and that various substances were produced within the body by decomposition under modifying circumstances, as, for instance, cholesterin, which sometimes forms biliary calculi. Leucine appeared to occur in different parts of the body, both normally and abnormally, and particularly in the pancreas; while, in the diseases classed under the name of atrophy, it appeared to be formed in the liver. The relation known to exist between alanine and lactic acid, the presence of which in the system is supposed to be the cause of rheumatic fever, had suggested the idea that there existed an acid body bearing a similar relation to leucine. This acid was already known, and a method of preparing it had been published in Liebig's *Annalen*—namely, by the action of nitric acid on leucine. In preparing this acid it was better to employ an excess of leucine; a mixture of leucic acid and nitrate of leucine would be obtained, from which the leucic acid might be separated by evaporating the solution, and treating the residue with ether; evaporating the ethereal solution, and drying the residue over sulphuric acid; or ether might be employed without previous evaporation; but the complete removal of the acid was then more difficult. The acid obtained in this manner was contaminated with an oily substance, which could be removed by pressure, or by solution in water. The properties of the acid were as follows:—It has when solid the consistence of hard soap; it reddens litmus, and decomposes alkaline carbonates; is soluble in water, alcohol, and ether, and fuses below the temperature of boiling water; on exposure to heat it gradually alters to an oily liquid, this same oily substance is always formed when a solution of the acid is heated. The composition of this substance is represented by the formula $C_{12}H_{12}O_6$, leucine being $C_{10}H_{12}NO_4$, from which it is evident that these bodies have the same relation to one another that lactic acid has to alanine. Nitroleucic acid was formed by the action of nitric acid; this substance was insoluble in ether, but if leucic acid was present it dissolved to some extent. Various salts of leucic acid were then described, more especially the lead and mercury salts, which when precipitated presented under the microscope an appearance resembling the yeast plant, and even seemed to grow in the same manner. The

composition of these salts was represented by the general formula $C_{12}H_{11}MO_6$.

Dr. H. BENCKE JONES read a paper "*On the Occurrence of Phosphate of Lime in the Human Urine.*" Various diseases had been supposed to give rise to such deposits in the urine, more especially diseases of the nervous system and the brain. Dr. Roberts had, however, pointed out that, by adding chloride of calcium and neutralization, a deposit of phosphate of lime could be obtained in the healthy secretion. It appeared that, by employing both these reagents together, a deposit could always be obtained, and that sometimes the addition of the lime salt alone was sufficient; at other times neutralization caused a deposit, no additional lime being necessary. Deposits were formed by mixing solutions of chloride of calcium and phosphate of soda; and the resulting compounds were compared with those obtained in urine. Doses of lime-water and of acetate of lime were given to a patient at St. George's Hospital who had been suffering from dyspepsia, and who had nearly recovered; a deposit was obtained with some difficulty, but a dose of one pint of lime-water daily, or thirty grains of acetate of lime, was always found to be sufficient.

Dr. THUDICHUM remarked that the crystals obtained by such treatment were often so minute that a microscope was necessary to discover their presence; also that bitartrate of potash and carbonate of soda, when given internally, would cause similar deposits, generally little globular concretions, in which the crystals radiated from the centre to the circumference, these concretions varying from the size of a pin's head to that of a pea, and consisting of pure phosphate of lime, oxalate of lime being also formed at the same time, and that the administration of nitric acid removed both these deposits.

The PRESIDENT inquired what was the composition of the phosphate of lime deposit?

Dr. BENCKE JONES replied, that that point had already been determined, the crystalline deposit being composed of two equivalents of lime, one of water, and one of phosphoric acid; and the amorphous compound of three equivalents of lime and one of phosphoric acid.

Mr. E. J. MILLS read a paper "*On Sparteine.*" A doubt had been raised as to whether the formula usually given for sparteine—namely, $C_{18}H_{13}N$ —was correct; in fact, Gerhardt, finding that it was difficult to represent the composition of this substance by his nomenclature, had concluded that the formula should be altered to $C_{17}H_{13}N$. It appeared that the best method of drying this substance was to treat it with sodium, for that exposure over sulphuric acid failed to remove all the water. A careful analysis of this body corroborated the formula originally given by Dr. Stenhouse; it appeared to be a diimine of a composition represented by the formula $C_{17}H_{14}N_2$, and homologous with nicotine, $C_{10}H_{14}N_2$. The salts of this base were described, the platinum salt had the composition $C_{17}H_{14}N_2 \cdot 2HCl + 2PtCl_2 + 2H_2O$; the gold salt, on the contrary, contained one equivalent each of chloride of gold and of chloride of sparteine. By the action of iodide of ethyl on sparteine, a compound of the composition $[C_{17}H_{13}(C_2H_5)_2N_2]^+I_2^-$ was obtained, which was not decomposed by caustic potash, and on treatment with oxide of silver gave the corresponding base. The platinum salt of this base was analysed, and compounds with chloride of zinc were formed. The action of iodide of ethyl on a solution of the base in methylated spirit gave a product, the composition of which was still doubtful.

Dr. STENHOUSE drew attention to the very small number of natural volatile bases that had been discovered, although a great many had been formed artificially.

Dr. ODLING said that a great variety of volatile bases were formed during the spontaneous decomposition of nitrogenous bodies. He also alluded to volatile bases that had been obtained from sewage.

The PRESIDENT remarked that trimethylamine had been

obtained as a product of the decomposition of human urine. He afterwards alluded to some compounds that he hoped soon to be able to produce from benzol and its homologues, bearing the same relation to the aniline compounds that the diatomic ethylene bases did to ethylamine. The action of reducing agents on binitrobenzol had been tried by different experimenters, with the view of forming a diatomic base, but with unsatisfactory results. He had, however, lately received from Dr. Oppenheim a crystalline body contained in the refuse from some aniline works at Paris, which, on examination, appeared to have the composition

This compound had been produced on account of the impurity of the benzol employed in the manufacture of aniline; toluol being present in some quantity. He had found that the action of metallic iron and acetic acid on binitrotoluol completely verified this conclusion. Binitrobenzol was then submitted to the action of the same reagents, and was reduced and furnished the corresponding base, salts of this base had been prepared, the chloride had the composition

With chloride of cyanogen and other reagents, the new compound underwent similar changes to the aniline itself. It was possible that besides these compounds, others corresponding to the ammonias of the highest order could be produced by changing the bases already obtained to nitro-compounds and acting on these by reducing agents.

It was announced that at the next meeting papers would be read by Dr. OPPENHEIM "*On the Camphor of Peppermint*"; Mr. G. C. FOSTER "*On Piperic and Hydro-piperic Acids*"; Professor BOLLEY "*On the Physical Properties of some Alloys of Lead and Tin*"; and "*On the Dangers Produced by Feeding Steam Boilers with Certain Waters*."

NOTICES OF PATENTS.

617. *Obtaining Fresh Water from Salt Water.* D. HENSON and W. G. RAMSDEN, Liverpool. Dated March 13, 1861.

THE arrangement of apparatus for carrying out this invention is described as being particularly applicable on board steam-ships, for the purpose of procuring by distillation supplies of fresh water from the sea. The steam boilers ordinarily working in connexion with the engine are likewise placed in communication with a cylindrical or other conveniently-shaped vessel containing the sea-water to be submitted to distillation. The pipes conveying the steam may either dip directly into the sea-water, or pass through this second vessel in the form of a coil or multitubular arrangement. In any case, the object of the invention, as stated by the patentees, consists in the employment of steam as a means of heating and causing the evaporation of salt water. From the upper part of the distilling chamber an exit pipe is led off, which conducts the steam therein generated through a worm tube or other condensing arrangement immersed in cold water. In this manner, a supply of fresh, drinkable water is procured by distillation at ordinary pressures; but, in the event of the steam-ship being provided with engines having surface condensers, it is proposed to open a communication between these latter and the evaporating vessel, with the intention of carrying out the process at lower temperatures by the creation of a partial vacuum.

In the construction of this apparatus there is an obvious anomaly in respect to the intervention of the second receptacle for sea-water. A very simple inter-

mediate contrivance would effectually prevent the escape of particles of liquid and solid matters which are liable to accompany the steam generated in the ordinary engine boilers. It would, therefore, surely be easier to procure the evaporation of the salt water at once from the boiler, than to proceed upon an indirect system of conducting steam from a marine boiler into sea-water in order to supply the heat requisite for re-converting the contents of the second chamber again into vapour. With reference to the suggestion for conducting the process of distillation under circumstances of removed pressure, it must be remembered that the difficulties attending the condensation will, in the same measure, be augmented, and the action of the condensers themselves impaired by this adaptation to a double purpose. The aerating arrangement which constitutes an important feature of Dr. Alphonse Normandy's apparatus is here altogether omitted.

622. *Apparatus used in the Manufacture of Paper.* J. L. JULLION, Tynemouth, Northumberland. Dated March 13, 1861.

It is customary to use a felt pad of woollen material for the purpose of receiving, draining, and drying the newly made sheet of paper; the patentees employ as a substitute a fabric made of cotton or other suitable vegetable fibre.

640. *Tanning Leather.* A. F. MENARD, Rue de Strasbourg, Paris. A communication. Dated March 14, 1861. (Not proceeded with.)

In this specification, which refers to a more expeditious system of tanning and preparing leather, the inventor enumerates a variety of physical conditions under which the process may be conducted; as, for instance, with the employment of a vacuum, or under increased pressure; by the injection of carbonic acid gas combined with the transmission of galvanic and electric currents, &c. &c. The subject of the eighth claim is, however, of a chemical nature, and relates to the employment of bisulphide of carbon, which, being a solvent for fatty matters, is said to have the property of rendering the leather more supple and pliable, and of conferring upon it superior waterproofing qualities.

The application of this fluid in conjunction with gutta percha and india-rubber, has previously formed the subject of a provisional patent, which will be found described at page 82 of the present volume.

642. *Certain Improvements in the Manufacture of White Lead and Other Salts of Lead direct from Ores Containing Carbonate of Lead.* JOHN ARTHUR PHILLIPS, Earl's Court, Kensington. Dated March 15, 1861.

A PROTEST having been entered against this patent prevents us from giving the particulars of the specification.

650. *Obtaining and Utilising the Chemical Products of Spent Bark commonly called Tan.* W. LARBERG, St. Mary-at-Hill, Eastcheap, London. Dated March 15, 1861.

THIS invention relates to the treatment of waste tan or other woody fibre by destructive distillation. When submitted to this process, the following substances are obtained as products:—Charcoal, tar and other oily matters, pyroligneous acid, and gas. The tarry substances may by a second distillation be made to furnish paraffin, creosote, and wood naphtha. The crude acetic acid may be collected in the ordinary way, or by the intervention of a metallic vessel containing alkali between the retort and condenser, the acid may be retained, without condensing much of the aqueous vapour, and the corresponding acetate produced in one operation. The permanent gas liberated during the process consists chiefly of hydrogen

and carbonic oxide, and may therefore at once be employed as a source of heat in assisting the action of the furnace; or by suitable means can be made to burn with a luminous flame, and consequently be applied to illuminating purposes.

The mode of fixing the free acetic acid in the distillate is likely to be found serviceable, but the methods of disposing of the gaseous products from wood, by rendering them available as sources of heat and light, have been anticipated.

652. *Manufacture of Gas.* F. TRACHSEL and T. CLAYTON, Manchester. Dated March 15, 1861.

THE improvements described in this invention relate to certain methods of producing light, and to apparatus for rendering hydrogen gas, carbonic oxide, and even atmospheric air and other gases luminous by the introduction of volatile substances of a combustible nature, and in such a manner that the air or gases so impregnated may be conveyed through pipes and burnt like ordinary coal-gas at its issue from properly constructed jets. The materials available for these purposes are the following:—Alcohol, ether, camphor, turpentine, and other essential oils, wood spirit, coal tar, naphtha, benzol, petroleum, and other mineral oils, caoutchouc, and similar substances. These matters are used either singly or in combination, and will be better adapted for impregnating the air or gases after they have been rectified by distillation, the products obtained below the temperature of 212 degrees Fahrenheit being preferred. When common air is to be charged with any of these hydrocarbon vapours the supply may be drawn from the atmosphere by fan blasts, bellows, gasometers, air pumps, wind-mills, or any other blowing contrivance. For the special purposes of heating hollow calendering rollers and of singeing textile fabrics, the patentees procure a suitable gas by the decomposition of steam by red-hot charcoal or scrap iron, the apparatus being made self-regulating by the action of a float valve governing the admission of the steam. For general illuminating purposes it is preferred to employ hydrogen generated by the action of acids upon corrodible metals, or the mixture of hydrogen and carbonic oxide as procured by passing steam over heated charcoal; these gases being subsequently rendered luminous by the employment of one of the hydrocarbons enumerated.

The practical suggestions contained in this patent claim include much that has already been accomplished; thus, the mode of rendering air and non-inflammable gases combustible and luminous by impregnation with benzol or naphtha vapour was carried out many years ago by the late Mr. Charles B. Mansfield, as we took occasion to remark in connection with the patent of Mr. E. C. Shepard, dated January 9, 1861,¹ for a similar application. The production of a gas suitable for heating purposes by passing steam over red-hot charcoal is a fact long known and identified under the name of "White's Water Gas." And, if in this last operation iron be substituted for charcoal with a view to the preparation of pure hydrogen, we have but another version of the patent No. 593 to which we refer (page 267) for remarks equally applicable to the present specification. It could be shown, finally, that two of the substances enumerated, viz., alcohol and wood spirit, have not the property of rendering luminous the flame of hydrogen or "water gas."

Grants of Provisional Protection for Six Months.

1796. Joseph Heape Butterworth, Vicars Moss Mills, Rochdale, Lancashire, "An improved mode of, and apparatus for, heating air or for desiccating wet or moist substances."—A communication from Jérôme Eugène

Tourné, New Orleans, Louisiana, U.S.—Petitions recorded July 17, 1861.

2162. James Simmons Matthews, Moore Cottage, Bowling Green Street, Kennington Park, Surrey, "Improvements in the manufacture and preparation of starch, and in the apparatus employed therein."—Petition recorded August 30, 1861.

2482. Thomas Goulston Ghislin, Hatton Garden, London, "Improvements in the treatment or preparation of certain foreign plants or vegetable substances, and in the application of the same to various useful purposes for which horn, shell, whalebone, indurated leather, fish skin, ivory, bone, hard wood, and compounds of india-rubber or gutta-percha have hitherto been employed."—Petition recorded October 4, 1861.

2707. Frederick Bennett, Bagillt, Flintshire, "An improvement in the manufacture of spelter."

CORRESPONDENCE.

Test for the Purity of Acetic Acid.

To the Editor of the CHEMICAL NEWS.

SIR,—I shall esteem it a favour if you would kindly insert the following in your next publication, for the benefit of those interested in the manufacture of pure acetic acid.

Whilst making experiments on pyroligneous acid with a view to make pure acetic acid, I have been at a loss for a delicate test to ascertain when the acetic acid is entirely free from "emphyreuma," which, hitherto, I have found very difficult (when so dilute as not to be tasted or smelt), and I am not aware of a good test for that purpose; but I have found, by neutralizing the acetic acid suspected to contain "emphyreuma," or "emphyreumatic oil," by carbonate of soda or potash and adding a solution of permanganate of potash (Condy's fluid), that, if pure, it remains pinky and unaltered, but if it contains the slightest trace of emphyreuma, the permanganate of potash is immediately decolorized, and after standing a short time, a brown precipitate is produced, but this is not the case when the acetic acid is absolutely pure.

I am, &c.

JOHN LIGHTFOOT.

On the Copper Test for Sugar.

To the Editor of the CHEMICAL NEWS.

SIR,—In reference to the Copper Test for Sugar, I have just made a few experiments to ascertain its amount of sensitiveness, and I find that a sensible precipitate may be obtained by the $\frac{1}{10}$ of a grain of sugar, which is much greater than Dr. Bence Jones' estimate, which is only $\frac{1}{20}$. This can be proved by boiling a drop of the sugar solution with the copper fluid in a capsule, and then projecting it into a test-glass and observing the precipitate which falls on cooling.—I am, &c.

JOHN HORSLEY.

Chemical Notices from Foreign Sources.

I. MINERAL CHEMISTRY.

Compounds of Ammonia with the Salts of Copper and Cobalt.—Schiff considers (*Comptes Rendus*, t. liii. p. 410) that the compounds of ammonium with the salts of copper may be derived from four ammoniums. ($\text{Am} = \text{NH}_4$.)

The author has obtained a variety of salts of the two first bases by decomposing the sulphate of amicupriconium with the various salts of baryta, or by dissolving the cupric salts in ammonia.

The salts of the peroxide of cobalt which contain the triatomic radical, $\text{Co}''' = 59$, give triatomic ammoniums; and the protoxide salts containing the monatomic $\text{Co}' = 29.5$, give a monatomic base, which under the influence of ammonia and oxygen will form an intermediate diatomic base.

The author intends to show in future papers that the compounds of ammonia with the peroxide of chromium, aluminium, iridium, and other triatomic metals, may be described as the above.

II. ORGANIC CHEMISTRY.

Spontaneous Decomposition of Gun-cotton.—M. Bouet (*Comptes Rendus*, t. liii. p. 405) has remarked that the decomposition of gun-cotton in diffused light is preceded by the appearance of a reddish atmosphere, and also that the cotton prepared with nitrate of potash and sulphuric acid is sooner and more violently decomposed than that prepared with the mixed acids. The residue, he says, is also different in the two cases: that of the first is something like burnt sugar, and in the second case is of a straw colour. In both cases the sides of the bottle were nearly covered with small crystals of oxalic acid, and the air contained had an acid reaction. M. Bouet demonstrated the presence of carbonic and formic acids in the atmosphere of the bottle, and he thinks it probable that cyanogen was present. No oxide of nitrogen was discoverable. The solid residue after the removal of the oxalic acid was white, and dissolved in water like gum.

M. Chevreul agreed with M. Bouet, but insisted that light was an active agent in decomposition only when air was present; and among other things he insisted on the importance of light in a sanitary point of view, the salubrity of a house greatly depending on the free admission of light as well as air.

Luca found, however, (*Ibid.* t. liii. p. 298) that gun-cotton which had been kept in the dark had undergone decomposition with the evolution of nitrous vapours. Nearly the whole of this "modified" cotton he found to be soluble in alcohol and in water—14 per cent. in the former and 78 per cent. in the latter. The products of the decomposition he intends to study further.

Transformation of Propionic into Lactic Acid.—MM. Friedel and Machuca (*Comptes Rendus*, t. liii. p. 408) heated propionic acid and bromine in a sealed tube and obtained bromopropionic acid which they found to act readily on oxide of silver in the presence of water. They then passed sulphuretted hydrogen through the silver solution and so procured a strongly acid liquor, which neutralized with oxide of zinc and evaporated yielded crystals exactly resembling ordinary lactate of zinc. Analysis, and the formation of other salts, confirmed the identity of the lactic acid formed as above with that obtained by the usual fermentation process.

Patagonian Guanos.—M. Malaguti gives an account (*Comptes Rendus*, t. liii. p. 436) of a few guanos brought from a group of small islands lying off Port Desire, on the coast of Patagonia. His analyses do not differ much, except in one case, from those published here; but the

guano brought from Penguin Island appears to be remarkable from the amount of phosphate of alumina it contains. The whole amount of phosphates which this guano, according to M. Malaguti, contains never exceeds 35 per cent., and the greater part of this is phosphate of alumina. This, the author remarks, is not a common fact; but what makes it more remarkable is, that in consequence of the presence of this salt, the earthy part of the manure is more soluble in acids before calcination than after. This is an important fact for chemists who are expected to give analyses of manures in a very short time. The phosphate of alumina is seen in the guano as a multitude of small white globules, which are easily reduced to powder by pressure. Only from 4 to 4.35 per cent. of nitrogen is present in Patagonian guanoes.

Blue Colour from Cotton Seed Oil.—Cotton seed oil is bleached by treatment with either carbonate of soda or caustic lime. In both cases a considerable residue is left after drawing off the bleached oil. This residue is treated with sulphuric acid, and distilled at a high temperature. There is then left, according to M. Kuhlmann (*Comptes Rendus*, t. liii. p. 444), a compact mass of a deep greenish blue colour. On further treatment of this mass with strong sulphuric acid, the green tint disappears, and a very intense pure blue colour is produced. Other acids, phosphoric and hydrochloric, will bring about the same change. The blue mass is a mixture of the coloured substance with some sulphuric acid, sulphate of soda, and fats. The two former may be removed by washing with water; the latter by treatment with naphtha. Alcohol now dissolves the blue colour, and water precipitates it from the solution chemically pure.

According to the mean of the results of three analyses, the composition of the new body was

C 70.24
H 8.35
O 21.41:

results which nearly agree with the formula $C_{24}H_{24}O_9$. The new matter could not be obtained crystallized.

Unhappily, M. Kuhlmann has not yet been able to dye with this colour, but he does not despair of fixing it.

Transformation of Cane Sugar into Pectic and Malic Acids.—Schoonbroodt (*Bulletin de la Société Chimique*, &c. No. iv. p. 77) mixed two parts of cane sugar with one of hydrate of lime, and then added three parts of pure and dry chloride of lime. This mixture he made into a thin paste with distilled water, and then let it alone for a time. A lively reaction soon set in, the mixture became heated, and chlorine was evolved. When the swollen mass was afterwards treated with boiling distilled water, it formed a bulky jelly, in which the author found among various other things, pectate of lime. Here is the explanation of the reaction:—

When the quantity of chloride of lime was doubled, a different result was obtained. In this case the reaction was slower, and the solution, though slightly gelatinous, would go through a filter. When this solution was evaporated to a syrupy consistence, and afterwards treated with alcohol, it deposited a white powder, which M. Schoonbroodt satisfied himself was mostly malate of lime. The malic acid, when isolated, behaved exactly like the natural acid. The formation of the malic is explained by the following equation:— $C_{12}H_{22}O_{11} + 3 CaOClO = 3 (C_4H_2O_4, HO) + 2 HO + 3 CaCl$. The author wishes to draw the attention of chemists to the above facts, assured that their researches will fully confirm all he has advanced. He is anxious also to have his claim to priority of discovery acknowledged.

MISCELLANEOUS.

Chemical Society.—The next meeting of this Society will take place on Thursday, December 5, when Papers will be read by Dr. Oppenheim "On the Camphor of Peppermint;" Mr. G. C. Foster "On Piperic and Hydropiperic Acids;" Professor Bolley "On Some Physical Properties of Tin-Lead Alloys;" and "On the Dangers Produced by Feeding Steam Boilers with Certain Waters."

Poisoning Noxious Animals.—On account of the numerous accidents which have occurred from using arsenic and phosphorus for this purpose, M. Séverin Causé, at the request of the French Government, has been pursuing a series of investigations with the object of devising some means of poisoning which should be as efficacious and more safe than those in use. As general principles he lays down these rules:—1. That we must not risk mistakes by employing the poison in the form of biscuits, pills, or powder; 2. An excipient must be used which is repugnant in taste to man but not to animals; 3. Emetic substances should be added, so as, in case of the poison being swallowed accidentally, vomiting may be produced, which is not with gnawing animals like rats and mice; 4. The substance should be easily detectable by chemical analysis; 5. The composition he finally recommended as the best suited as a destructive agent, consists of tallow 786 grammes, tartar emetic 153 grammes, and euphorbium 51 grammes. These, mixed with a pinch of aucturine (added for facility of detection in case of human poisoning), by the aid of 10 grammes of cotton, are made into thirty-two candles, each of which would suffice to poison several rats or mice.—*Annales d'Hygiène*, vol. xv., p. 425.

Scientific Education.—Perhaps there never was a time when scientific knowledge was at a greater premium than it is at present. The system of competitive examination, now so common in the Government departments, and especially in the Indian Service, has created a considerable demand for scientific education. Unhappily, this demand has hitherto been very inadequately met. Scientific instruction has, with rare exceptions, been quite foreign to the ordinary curriculum of our upper and middle-class schools. Amongst the honourable exceptions must be classed the Scientific and Engineering School attached to the College at Chester, under the principalship of the Rev. Arthur Rigg, F.S.A. This gentleman, himself of high scientific attainments, was one of the first, if not the first, to recognise the increasing importance of scientific education to the youth of England, and it was at his suggestion and through his exertions that the Chester School was established. Its success has demonstrated the soundness of Mr. Rigg's views. The school has long been held in high repute by scientific men, and we are glad to learn that the Secretary of State for India has formally recognised it "as possessing an efficient class for civil engineering." There is one feature peculiar to this school which we should like to see more common,—a portion of each day is set apart to work in the laboratory and workshops. Thus, theory and practice are combined. We shall be glad if the success of the Chester School leads to a more general introduction of the scientific element into middle-class education.

Alchemy in the Nineteenth Century.—The following astounding *canard* is being extensively quoted in American papers:—"It has been a great mystery to English bankers, and to the Directors of the Bank of England, how the bullion of the Bank of France could be so greatly increased within the last three years, while the institution has been constantly sending gold to England,

to Germany, and to America. Not long since the Bank of France drew some fifteen millions francs in silver from the Bank of England, which it paid for in gold bars with the French Mint stamp on them. At its last report it showed a balance of one hundred and seventeen million francs in gold, while the amount one year ago was under eighty millions,—nearly one-third increase. It is whispered that this abundance in gold is the result of a scientific discovery, which the Emperor Napoleon has secured the monopoly of. Gold is at the present moment manufactured at Paris in a secret manner. The principal articles used are lead and arsenic, and though it is not known how extensively the precious metal is produced, yet several hundredweight of the material are taken to a certain place on the 1st of each month. Everything is conducted with the utmost secrecy. None of the workmen are allowed to leave, and nothing definite can be known; but the fact that gold is produced is beyond peradventure. How long Napoleon III. will be able to keep this wonderful secret remains to be seen."

Spontaneous Generation.—The question of spontaneous generation is one of the subjects proposed for competition by the Institute, and communications are occasionally forwarded to that body by those who are likely to appear as candidates for the prize. Thus, at a recent meeting, M. Pasteur presented a work in which he endeavours to prove that all organized productions which appear in previously heated infusions, are due to the microscopic organised particles floating in the air. Another communication was also received from M. Jodin. This gentleman states that, on May 12, 1859, he took six glass tubes five inches long, and of a diameter of from seven to eleven lines, and hermetically closed at one end. Each tube received equal parts of crystallized sulphate of soda and water to about one-fourth of their capacity. Three, moreover, received a weight of sugar-candy equal to one third of the sulphate of soda employed. All the tubes were then heated in a water-bath, to liquefy their contents, corked and kept inside a press, in a vertical position. At the expiration of a twelvemonth, M. Jodin examined the tubes and found that the contents of all those which had only received sulphate of soda were totally crystallized, while those which also contained sugar had remained liquid; but this liquid was covered with a pellicle formed by a well-developed mycodermic vegetation, possessing the peculiar greenish hue of the spores of the *Penicillium glaucum*. Five minutes after the corks had been carefully removed the liquid crystallized in one solid mass. Hence it appears that the germs of the genus *Mucedina* (or mildew) may be developed and organised in contact with a solution of sulphate of soda, the particles which are arranged in that peculiar way which constitutes a state of excessive saturation.

Canadian Iron Ore.—In an account which appeared in the *Times* of the 26th inst., describing the loss of the Montreal steamship, *North Briton*, there is an interesting statement made relative to the occurrence of vast deposits of iron ore on Mingan, one of the Paroquite Islands in the Gulf of St. Lawrence, near which the ill-fated vessel struck and foundered. The rocks in the vicinity are said to be so greatly impregnated with iron as seriously to affect the action of ships' compasses. If this observation be correct, it points not only to the existence of vast mineralogical treasure in these islands, but affords hopeful indications in regard to the quality of these beds of ironstone; since the magnetic ores are those which at the same time exert the most powerful attraction upon the compass needle, and are distinguished for their purity and freedom, especially from those contaminations which most seriously prejudice the quality of the iron when manufactured. The finest brands of Swedish and Russian iron are known to be smelted from ores of the magnetic oxide class, and iron is largely produced on the continent of North America from similar

sources. Large supplies of pig iron from the adjoining territory of Nova Scotia have been brought into the English market; and it would be interesting to know whether the beds of ore referred to in the foregoing narrative, have hitherto been turned to practical account.

Arsenical Poisoning.—An inquiry has this week been held by Mr. G. S. Brent, touching the death of Matilda Scheurer, a good-looking girl, aged 19, who died from poison imbibed into the system during her engagement in the manufacture of artificial flower leaves. Mrs. Louisa Scheurer, a widow, and mother to the deceased, deposed that on Thursday week her daughter was taken ill. She was seized with vomiting and the refuse of the stomach was of a very greenish colour. The witness took her to a doctor on the following morning, who told her she was again suffering from the effects of poison. She had been ill several times before, complaining of pains in the stomach and sickness, for the last year and a-half. She was engaged as an artificial florist in the warehouse of M. Bergerond, of Judd Street, Brunswick Square, and up to the time of her death she had been engaged in the leaf-making. She was in the greatest pain until she became insensible, when death put an end to her sufferings. Mr. James Thomas Paul, surgeon, of 26, Burton Crescent, said he had attended the deceased four times within 18 months, while suffering from the same causes. He had made a *post mortem* examination, and found that the lungs gave evidence of the presence of arsenite of copper, the liver being highly impregnated, as also the mesenteric glands. The cause of death was acute inflammation of the mucous membrane of the stomach, produced by the inhalation of the arsenite of copper. A sister of the deceased had died under similar circumstances. M. Bergerond said he employed 98 girls in his establishment, and for their protection he had suggested the wearing of masks, but it was objected by them as producing excessive heat. They, however, wore muslin over their mouths. It was stated by a juror that the arsenite of copper in such manufactures was prohibited in France, as injurious to workpeople. The jury returned a verdict to the effect that deceased died accidentally, from the effects of mortal disease in her stomach and other organs, occasioned by arsenite of copper used in her employment.—*Times*.

New Scientific Society.—A Society has recently been formed in Manchester, under the title of the "Scientific Students' Association." This Society owes its origin to a few scientific tyros, who, having experienced great pleasure and profit from attending the sectional and other meetings of the British Association, during the late visit to Manchester, determined to form a little Association for the benefit of the Manchester lovers of science. Mr. L. H. Grindon consented to act as Chairman, and a Committee and other officers were at once appointed, consisting mainly of the originators of the scheme. The members meet, for the present, once a fortnight, for the purpose of hearing and discussing papers on subjects connected with physical and natural science, which are illustrated, as far as possible, by specimens, experiments, diagrams, the microscope, &c. Excursions will also be occasionally arranged.—*Engineer*.

H. W.—We do not think that there is any waterproof cement known which is sufficiently strong to be used for joining broken false teeth or similar small articles when they are to be subjected to rough usage. You will find a useful series of cements described in Beasley's Druggist's Receipt Book.

Otto Richter.—Received with thanks. In our next.

THE CHEMICAL NEWS.

VOL. IV. No. 105.—December 7, 1861.

THE COMPOSITION OF THE SOLAR SPECTRUM.

In another column will be found two papers on this subject, which merit serious attention on account of the modifications which they appear to render necessary in the recently-suggested explanation of the constitution of the sun's atmosphere. In Kirchhoff and Bunsen's original paper on "Spectrum Analysis," they state, that "the appearance of the spectrum can vary considerably. If the intensity of the light be increased, new lines appear in several of the spectra (of the alkalis), and the relation of the brightness of the old ones becomes altered. In general, an indistinct line becomes brighter upon increasing the illumination, more rapidly than does a brighter line, but not to such an extent that the indistinct line ever overtakes in intensity the brighter one. A good example of this is seen in the two lithium lines." This circumstance appears, however, to have attracted no particular attention, and many of our readers remember the incredulity with which Dr. Tyndall's first exhibition at the Royal Institution, of a magnificent blue band as a constituent of the lithium spectrum, was met by the chemists present. The almost unanimous opinion was, that he had by a *lapsus linguae*, used the word lithium for strontium throughout the evening. Dr. Frankland's article, with Dr. Tyndall's note, given in our present Number, fully clears up the apparent difficulty; whilst, at the same time, it tends to throw doubt upon some of the speculative generalisations which have been deduced from the recently-observed phenomena of the reversal of the bright spectral bands.

Taking Bunsen's estimates of the temperature of flame as correct, it is seen that the Bunsen's-burner flame (2350°C.) is not hot enough to produce the blue line of lithium, but the hydrogen flame (3259°C.) is able to bring it out. An increase of 909 degrees of temperature is, therefore, sufficient to increase by one-half the lines of lithium, whilst the heat of the electric arc raises the number of sodium lines from one to four. The same fact which Dr. Frankland has shown with regard to lithium and sodium we have proved in the case of potassium, calcium, strontium, barium, and copper; so that it may be fairly assumed, as a general law, that all spectra of incandescent elements become more complex as their temperature is raised. Now, the temperature of the sun's surface is, according to the most trustworthy authorities, stated to be equal to that due to the com-

bustion of $\frac{1}{4}$ th of a ton of coals per hour on each foot of surface; whilst Kirchhoff's theory necessitates a temperature at which iron would be a gas. In either case the heat would as far exceed the temperatures which can be produced by artificial agency as the sun's light surpasses our terrestrial means of illumination. What, then, will be the appearance of the spectrum of a metal when exposed to the exalted temperature of the sun's surface? We are not justified in assuming that its growth in complexity stops at a certain temperature, the heat increasing, but the lines remaining the same. Experiment tends to show that the spectrum of a solar element is quite different to that of the same body when experimented upon in our laboratories. It would contain, in addition to the lines capable of being rendered visible by terrestrial means, a vast number of lines which only the solar temperature can evoke; and, consequently, it is exceeding the legitimate inferences to be drawn from experiment, for physicists to assume that the reversal of a few prominent lines in artificial spectra proves the metallic constitution of the sun's atmosphere. Unquestionably certain metallic lines can be reversed, but the black bands thus artificially produced in a continuous spectrum are very dissimilar in sharpness, width, and, in some cases, according to M. Morren, even in position, with the Fraunhofer lines, with which they are supposed to correspond; whilst the sharpness, nearness together, and enormous number of the solar lines are such that it would be difficult to find a line which did not correspond in position to a reversed artificial line.

Granting, however, that the differences of width and sharpness between the artificially reversed and the solar lines may be accounted for by the relative temperatures of the luminous and intercepting flames not being properly proportioned one to the other, we still think that our knowledge is at present too imperfect to justify the classification of a metal as a constituent of the sun on the strength of a few observed coincidences between the solar and the metallic fixed lines. M. Morren has shown that the so-called soda line D is a constituent of several metallic spectra besides that of sodium; unless, therefore, it can be shown that every line capable of being evolved from an incandescent metallic gas at the highest attainable temperature is accurately represented by a black Fraunhofer line, we cannot admit the accuracy of the deductions, but must consider the coincidences as merely accidental, and in no way related to one another in the manner of cause and effect. For instance, the line D being a constituent of the mercury spectrum, the presence of sodium in the sun's atmosphere cannot be proved by this line alone, but must be shown to be probable by an examination of the blue bands mentioned by Dr. Frankland; and in a similar way only can the probable existence of other metals in the sun be shown, not by a reversal and comparison of one or two lines merely, but by proving that every line which it is possible to see at the highest temperatures can be reversed into its counterpart in the solar spectrum.

SCIENTIFIC AND ANALYTICAL
CHEMISTRY.

Researches on the Relations existing between Atomic Weights, by M. J. S. STAS, Member of the Royal Academy of Belgium.

(Continued from page 283.)

Determination of the Proportional Relation between Silver and Chloride of Ammonium.—

Upon glancing at the determination of the proportional relation between silver and chloride of ammonium performed by M. de Marignac, it is perceived that they differ considerably from one another; between the minimum and the maximum there is a $\frac{1}{100}$ th, — a difference five times greater than the error which belongs to the method followed by this skilful chemist. When I commenced my researches I noticed an analogous fact. After long experimental trials I succeeded in discovering the cause. It is occasioned by the property which sal-ammoniac possesses of absorbing an excess of acid. This salt, which naturally has a very decided acid reaction, even when it has been produced in the midst of a very ammoniacal medium, holds an excess of acid when it condenses after having been very strongly heated in the state of vapour.

Heat in effect decomposes sal-ammoniac, with production of nitrogen and hydrogen, and a part of the hydrochloric acid which is set at liberty condenses with the vapour of the sal-ammoniac. This double property possessed by sal-ammoniac, in common with many other ammoniacal salts, of reddening test-paper, and taking, besides, a slight excess of acid, constitutes an additional difficulty in the determination of the proportional relation of this body. With the object of overcoming this, I attempted to determine in each specimen of the salt the quantity of hydrochloric acid which there was in excess; but I especially made all possible efforts to prepare sal-ammoniac without excess of acid, in order to avoid making a correction which is uncertain.

This uncertainty arises from two causes. The naturally acid reaction of sal-ammoniac, supposing it to be of neutral composition, evidently represents a certain quantity of base; but this quantity is unknown, and there is no means of determining the amount *a priori*, and it is only by comparison that one can acquire the certainty that the degree of acidity is not identical. The method which can be employed to estimate the excess of acid is not susceptible of the precision which it ought to have in order to give absolutely exact numbers. This is evident upon examining my results with attention.

The means which I have employed to estimate this degree of acidity consist in searching how much standard solution of lime must be added to bring a given weight of the salt to neutrality, measured by litmus or turmeric.

The standard lime-water contained per cubic centimètre a quantity of base represented by 0.0003201 grammes of hydrochloric acid. It was, therefore, excessively weak, so as to require a considerable volume of liquid, and also to allow me to appreciate the smallest quantities.

In the specimens of chloride of ammonium which I have prepared for my experiments the degree of acidity varied from the $\frac{1}{100}$ th to the $\frac{1}{1000}$ th part of the weight of the chloride, supposing, be it understood, that the acidity is due to loss of ammonia. But, as I have already observed, the chloride of ammonium formed in the midst

of a highly ammoniacal medium still reddens litmus. This supposition is, therefore, inexact, and the figure obtained necessarily includes an error, the amount of which may even be greater than the minimum quantity stated.

As I believe I have succeeded in preparing at will sal-ammoniac possessing an acidity which is scarcely superior to that which belongs to the definite compound, the difficulty which I attempted to overcome is no longer of any consequence. Indeed, I only mentioned it to explain the disagreement which the results obtained by M. de Marignac show between themselves, and the difference which may be remarked between the first four determinations and the ten following ones.

All chemists have remarked the difficulty which there is in procuring sal-ammoniac capable of volatilising without leaving any residue. Sometimes there remains a carbonaceous matter; sometimes a mixture of silica, alkaline chloride, and oxychloride of iron is obtained. Indeed, commercial sal ammoniac and the ammonia obtained from it contain compound ammonias which furnish this carbon; it also contains chloride of iron. The alkaline chlorides and the silica which is found in the residue of the volatilisation of sal-ammoniac are derived from the vessels in which the operation has taken place.

The precautions which I have taken in the preparation of the chloride to be used in my determinations have had for their object the getting rid of these impurities. It would be too long to detail here all the tedious processes which I have adopted to obtain sal-ammoniac free from all foreign substances; it would, moreover, be without interest. I will content myself with pointing out the methods employed to prepare the products which I have experimented upon.

I. Chloride of Ammonium from Commercial Sal-ammoniac.—I have purified commercial sal-ammoniac with a double object: first, to make use of it in my determinations; and, second, to extract from it pure ammonia with which to prepare the chloride of ammonium required for the treatment of the chlorides of potassium and sodium.

To destroy the compound ammonias existing in commercial sal-ammoniac, I had recourse to the following means:—A boiling saturated solution of sal-ammoniac, freed from iron and other metals by sulphide of ammonium, is mixed with a twentieth of its volume of concentrated nitric acid. The mixture is evaporated away from all organic dust. The residue being dried, is moistened again with a small quantity of nitric acid, and evaporated a second time to dryness. The compound ammonias are thus totally destroyed, with a very notable quantity of the sal-ammoniac itself.

It is from this salt, so purified, that I have extracted the pure ammonia employed in the preparation of the chloride of ammonium used in the treatment of the alkaline chlorides, by combining it direct with pure hydrochloric acid.

To transform the purified salt into pure chloride of ammonium, I sublimed it three successive times at the lowest possible temperature. The salt collected in the neck of the flask during the first sublimation always contains traces of bisulphite of ammonia. On this account I have taken to set apart all the chloride adhering at each sublimation to the neck of the flask. While the sublimed sal-ammoniac remains very warm, it is as transparent as glass, and possesses extraordinary elasticity. Upon cooling, it becomes more or less opaque, and then loses its elasticity in a remarkable manner.

The determinations Nos. I., II., III., and IV. were made with the aid of sal-ammoniac thus obtained. It was perfectly colourless, and volatilised without the least residue. As may be seen by a comparison of the results, they possessed very different degrees of acidity. The specimens submitted to experiment were taken from portions considerably removed one from the other. A portion of sal-ammoniac was sublimed a fourth time, but in an atmosphere of dry ammonia. The result given at No. V. refers to this chloride.

Another portion of the same salt was dissolved three successive times in ammoniacal water, and the salt, after drying, heated until it agglutinated. The result which it yielded on analysis is given at No. VIII.

II. Chloride of Ammonium from the Action of Pure Ammonia and Carbonic Acid upon Pure Chloride of Calcium.—I have had recourse to this mode of preparation in order to obtain at the same time a certain quantity of pure carbonate of lime.

Some beautiful white marble was dissolved in pure hydrochloric acid. The chloride of calcium so obtained was boiled with a little milk of lime prepared by means of lime from the calcination of marble in a platinum vessel. The solution of the basic chloride of calcium was filtered and evaporated to dryness; the residue was fused in a platinum vessel.

This chloride was perfectly colourless. Taken up with cold water, the alkaline and turbid solution having become clear by standing, was poured into pure water in which I had dissolved pure ammonia extracted from sal-ammoniac which had been twice treated with nitric acid. The mixture was submitted to a current of carbonic acid to the complete precipitation of the lime. The colourless and slightly ammoniacal solution was evaporated to a pellicle. The crystallised salt, separated from its mother-liquor, was dried and then twice sublimed. It was absolutely colourless at the first sublimation, and left no trace of residue at the second sublimation. No. VI. refers to the result furnished by this salt.

A portion of the preceding salt was dissolved in ammoniacal water and the solution evaporated *in vacuo* over fused potash. The resulting chloride was sublimed in platinum at the lowest possible temperature. No. VIII. gives the result of this experiment.

Another portion of the same salt was dissolved in ammoniacal water. After the crystallisation of the chloride, the alkaline mother-liquor was decanted, and the salt, which already had a decided acid reaction, was exposed under a bell-jar with caustic potash. After thorough drying, it was submitted, in the same tube in which it was to be weighed, to a current of pure dry ammonia for an entire day. The next day the current of ammonia was replaced by air freed from all foreign substance, and the current was continued for several hours after the air had ceased to carry off ammonia. The result of this experiment, made with extreme care, is found at No. IX.

III. Chloride of Ammonium Prepared by the Direct Combination of Pure Ammonia with Pure Hydrochloric Acid.—The ammonia displaced by an alkali from the chloride purified by means of nitric acid and carefully washed in water, was dissolved in water contained in a platinum vessel. The liquid, the ammoniacal odour of which differed completely from that of ammonia extracted from commercial sal-ammoniac, was then nearly neutralised with pure hydrochloric acid. Whatever might be the excess of ammonia existing in the liquid, the salt which was deposited by the action of the hydrochloric acid always presented a

decided acid reaction. This salt was dried in a current of dry ammonia and the ammonia then eliminated by a current of air. It took ninety-six hours to drive off the last trace of condensed alkali. The result given at No. X. refers to this salt.

This same chloride of ammonium volatilised in a platinum vessel in an atmosphere of ammonia and then weighed *in vacuo* gave the result at No. XII.

Wishing to satisfy myself of the influence of the ammoniacal atmosphere during the volatilisation of the salt, I sublimed the preceding chloride of ammonium a second time in platinum, the salt being weighed equally *in vacuo*. The result I obtained is shown at No. XIII.

Finally, I wished to form sal-ammoniac from ammonia produced by the reduction of nitric acid. With this object, I reduced nitric acid by a mixture of zinc, sulphuric acid, and water. The solution of the sulphates of zinc and ammonia thus obtained was concentrated and then poured on to hydrate of lime contained in a large retort. The mixture was heated, to drive off the liberated ammonia, and the gas, after being washed in water, was dissolved in pure water. The ammoniacal solution presents, as to its odour, the same difference from the ammonia extracted from commercial sal-ammoniac that I have recently mentioned in the case of that derived from the purified salt. It is incontestable that the gas possesses a much purer and infinitely less disagreeable odour.

This ammoniacal solution was nearly saturated with pure hydrochloric acid and allowed to crystallise under a bell-jar with solid caustic potash. The alkaline mother-liquor was poured off and the salt dried under a bell-jar with solid potash, and then in a current of dry ammonia, afterwards replaced by a current of dry, cold air.

The resulting chloride of ammonium was of a dazzling whiteness. It was weighed in the air and gave the result at No. XI.

I evaporated to dryness the voluminous mother-liquors from which the salt had been deposited, and mixed the resulting chloride with a great excess of fused and pulverised potash. The ammoniacal gas, dried by passing through two long U-shaped tubes filled with fused and pulverised potash, was directly combined with dry, pure hydrochloric acid, in a platinum digester holding five litres, taking the precaution always to keep the ammonia in excess. The sal-ammoniac produced, which was of extreme whiteness, was heated in an atmosphere of dry ammonia until it cohered together. It was then introduced into a glass tube and submitted to a current of cold and dry air until it had lost all the condensed ammonia. It was then weighed *in vacuo* and furnished the result given at No. XIV.

To enable the following Table to be understood, I must explain that it first shows the proportional relation between silver and sal-ammoniac given by the experiments, without taking account of the excess of acid which this compound retains or may retain; and, second, according to the hypothesis that the excess of acid is saturated with ammonia, and that the weight of the salt is proportionally increased. From a comparison of the two results, it is evident that chloride of ammonium can retain an excess of hydrochloric acid, but they show, at the same time, my inability to measure exactly the degree of acidity.

Upon examining this Table, it will be seen that the results are nearly constant from No. V. When I executed the first four determinations I was ignorant of the property possessed by chloride of ammonium of retaining an excess of acid under the above-named circum-

stances. In the ten following operations I succeeded in avoiding the excess of acid. Only the latter experiment could show if the compounds that I employed in the determinations could not in their turn retain an excess of ammonia. I can only say that I have used all my endeavours to avoid this cause of error.

Upon comparing the results furnished by those specimens of chloride of ammonium which were crystallised from a liquid, a slight difference may be remarked according to whether the weighing was effected in air or in a vacuum. The weighing in air is affected by an error on the plus side, owing to the condensation of this fluid by the salt. This cause of error will be easy to rectify by a subsequent experiment; I perceived it too late to take account of it.

If it is wished to calculate the mean of my experiments, it seems to me, in this case, the last ten only ought to be taken into consideration. This mean is 49'5944. Whence it results that the proportional relation between silver and chloride of ammonium is as 100,000 to 49'5944.

Determination of the Proportional Relation between Nitrate of Silver and Chloride of Potassium.—I have attempted to determine the proportional relation between nitrate of silver and chloride of potassium, in order to submit my syntheses of nitrate of silver to a rigorous control. It may be conceived that if the salt produced in these syntheses retains an excess of acid or of water, its presence could be proved in this manner. This research, moreover, would serve to verify Prout's law.

On this subject I have made three series of experiments. The first was executed with nitrate of silver prepared from pure silver, and which, after having been fused, was crystallised a great many times. The last crystallisation was hastened by cooling the liquid rapidly, so as to obtain the salt in a fine state of division. The salt, after having been kept away from the light for more than six months, under a bell-jar, with sulphuric acid, was fused and kept in this state in a current of air deprived of organic matter until its weight was constant.

The second series was made with the nitrate of silver described under No. VI. of the Table of the synthesis of this salt (CHEMICAL NEWS, Vol. IV. p. 244).

For the third series I employed a new nitrate of silver, obtained by dissolving in nitric acid the silver produced by the electrolysis of argento-cyanide of potassium. The salt was fused and dried as in the synthesis of the nitrate. The chloride of potassium employed was a portion of the same body which had served to establish the comparison with silver.

The nitrate of silver of the three experiments was white, lamellar, and of a pearly lustre. Its solution was neutral to test-paper. Before being weighed it was broken into small fragments, then heated in a platinum crucible, and introduced, as warm as possible, into the tube in which it was to be weighed after cooling. The tube was placed under a bell-jar with concentrated sulphuric acid. At each weighing of the nitrate I have stated the uncertainty which it presents. Nothing is easier than to get the weight of ten, twenty, or thirty grammes of chloride of potassium to almost the tenth of a milligramme; but, on account of the hygrometric property of nitrate of silver when fused and broken up into small fragments, I am not certain of the weight of an equal quantity of this salt to about one and a-half milligrammes. It was on this account that I determined to make a third series of experiments, weighing the broken-up nitrate of silver this time *in vacuo*, previously heated and then cooled likewise in a vacuum.

The weights of the nitrate and chloride were taken according to the relation deduced from Prout's law, taking for the equivalent of nitrate of silver 170, and that of chloride of potassium 74'5.

The nitrate was first introduced into a flask, and then dissolved in thirty-five times its weight of pure water, to ascertain its complete solubility.¹ The solution was mixed with four cubic centimetres of pure nitric acid per gramme of nitrate, and decomposed by the alkaline chloride. The operation was then concluded absolutely

¹ Nitrate of silver may contain traces of chloride and still produce a clear solution if dissolved in less than ten times its weight of water.

in the same manner as for the proportional relation between silver and the alkaline chlorides.

(1) In the Third Series all the weighings were performed in *vacuo*.
(2) Thus in the original paper: evidently a misprint for 12.59655.
(3) Determination of the Proportional Relation between Nitrate of Silver and Chloride of Ammonium.

I have sought for the proportional relation between these two bodies to control, at the same time, my syntheses of nitrate of silver and the relation which I found to exist between this metal and chloride of ammonium. I took for these determinations a portion of the nitrate of silver which served for the first two series of experiments with chloride of potassium.

I employed the sal-ammoniac of No. XI. for No. I.; of No. XII. for No. II.; and of Nos. XIII. for Nos. III. and IV.

(To be continued.)

Chemical Researches on the Assay of Silver by the Moist Way, by G. J. MULDER, *Math. Mag. Phil. Nat. Medicinæ, Artis Obstetriciæ et Pharmaceuticæ Doctor, Professor of Chemistry at the University of Utrecht, Grand Cross of the Order of the Netherlands Lion; of the Luxembourg Order of the Couronne de Chêne; of the Swedish Orders of Wasa and Polar Star, &c., &c.*

(Continued from page 232.)

In both the experiments above mentioned,—viz., 1 gramme and 3 grammes silver, temperature 15° to 17° C., the quantities of 20 and 60 drops of the decimal solutions were respectively required in order to produce, just to the extreme limit thereof, the mutual precipitate. 20 drops are exactly contained in 1 cubic centimetre; hence what holds good for 1 gramme of silver holds good also for 1 milligramme of silver, or an equivalent quantity of common salt,—viz., 0.54 milligramme; for 3 grammes of silver it likewise holds good for 3 milligrammes of silver or 1.62 milligrammes of chloride of sodium. With these quantities, viz.:

1 milligramme of silver, 3 milligrammes of silver, or 0.54 milligramme of salt or 1.62 milligrammes of salt are equivalent:

1.33 milligrammes ClAg; 3.99 milligrammes ClAg;

These, to be sure, are quantities which may even be of some consideration in the practice, while as far as pure science is concerned, it is the indication of the measure of that quantity, which gets withdrawn from the precipitation.

We will now see more about the solubility of chloride of silver in solution of nitrate of soda. We have already seen that, at least at higher temperature, this solubility of chloride of silver in nitrate of soda does really exist. If we are forced to assume that, according to what we have already learned, the solution, whether brought to the neutral point, or above, or below it, contains,—

then the whole matter is elucidated, provided the solubility of chloride of silver in nitrate of soda be proved at the same time, for nobody can practically demonstrate a difference between

It is first to be seen to what amount the solubility of chloride of silver in nitrate of soda ought to go in order properly to account for the phenomenon.

1 milligramme of silver yields 1.33 milligrammes of chloride of silver. 0.541 gramme chloride of sodium in 100 cubic centimetres of the standard solution, yield 0.787 grammes nitrate of soda dissolved in 100 cubic centimetres of water. Under the circumstances just mentioned, 0.787 milligramme of nitrate of soda dissolve 1.33 milligramme of chloride of silver, or 592 parts of nitrate of soda 1 part of chloride of silver.

If chloride of silver, at a temperature of from 15° to 17° C., is to such an extent soluble in solution of nitrate of soda, then the whole phenomenon must be referred to solution,—viz., in the sense defined by Berthollet.

This solubility of chloride of silver in nitrate of soda was rendered more evident by the following experiments, which also were made to illustrate the practical bearing of the phenomenon here spoken of:—

1. One gramme of pure silver was dissolved in 5 cubic centimetres of nitric acid, and afterwards just brought

to the utmost limit of precipitation, first by means of 100 cubic centimetres of the standard solution, and then a few drops of the decimal solution of salt. The temperature was 17° to 18° C. After this 22 drops of decimal solution of silver, and again 22 drops of decimal solution of salt were needed in order to precipitate every time unto the limit.

II. The same experiment as that just mentioned was made at the same time with 1 gramme of pure silver also, but to the solution of silver were added 2 grammes of pure crystallised nitrate of soda, 100 cubic centimetres of the standard solution, and a few drops of the decimal solution of salt produced the precipitate to the utmost limit. When, now, immediately afterwards, the decimal solution of silver and salt were added in every case to the limit of perceptible precipitate, then with silver again, and again salt, the drops being added two by two, the following result was obtained:—

Silver.	Salt.
A 38	B 38
C 38	D 38

Instead of 1.1 cubic centimetres or 22 drops, as in Experiment I., there was required 1.9 cubic centimetres of the solutions of silver and salt in order to produce the precipitate to the limit. From the common salt contained in 100 cubic centimetres of the standard solution, 0.787 grammes nitrate of soda is made by its reaction upon the nitric acid of the nitrate of silver. In every ordinary assay, therefore, that quantity of nitrate of soda is present.

In Experiment II. 2 grammes of nitrate of soda had been added, so that with the 0.787 gramme formed during the assay, 2.787 grammes were present. If we wish to assume the solubility of chloride of silver in nitrate of soda, we are already previously informed that in an ordinary assay 1 part of chloride of silver is soluble in 592 parts of nitrate of soda dissolved in 100 cubic centimetres of water. Experiment II. taught us that 2.787 grammes of nitrate of soda dissolve 1.9 milligramme of silver, equal to 2.527 milligrammes of chloride of silver, —i. e., 1 part of chloride of silver finds 1103 parts of nitrate of soda dissolved in 100 cubic centimetres of water.

There remains now to inquire what effect water alone has in dissolving chloride of silver. In order to elucidate this, two experiments were made at the same time and under fully the same circumstances, the only difference being that 100 cubic centimetres of pure water were mixed with the solution of silver, which contained 1 gramme of pure silver. The solution to which water had been added required 5 drops more of the decimal solution of salt than the solution prepared without this extra addition.

In this experiment, made at 16.5° C., we see that the water alone, which dilutes the nitrate of soda, increases the solubility of the chloride of silver in the former salt. On applying the decimal solution of silver, in order to bring the solution last mentioned just to the limit of precipitability, but no further, I found that 29 drops were required for the solution to which 100 cubic centimetres of water had been added, while the other only required 20 drops. The difference of nine drops, expressed in silver, is 0.45 milligrammes,—i. e. 0.6 milligramme more of chloride of silver had been dissolved by 100 cubic centimetres of water.¹ From these particulars, in connection with those previously stated, it follows:—

¹ We see there is a difference of half a drop between 5 and 9; 5 must either be 4, or 9 must be 10. From what has been already said, it is evident that the one must be just the double of the other.

1st. That it is in fact the nitrate of soda which gives rise to the production of the mutual precipitate of silver and salt.

2nd. That when the quantity of nitrate of soda is increased in the solution, the quantity of dissolved chloride of silver is also increased.

3rd. That the quantity of water present at the same time has an influence as well as the quantity of nitrate of soda.

I have, in speaking of this phenomenon, used the expression "solution of chloride of silver in nitrate of soda." It will hardly be necessary to remind the reader that this is precisely an instance of what has been more clearly indicated by Berthollet. What takes place in the experiments for the assay of silver on a smaller scale, finds place on a larger scale when, for instance, sulphate of potassa and chloride of calcium, both in solution, are mixed. Then there is formed chloride of potassium and sulphate of lime; but the sulphate actually precipitated is far less in quantity, than what has been formed in reality. We will keep, for simplicity's sake, the word "solution," the true signification of which we have given in the earlier pages of this treatise.

I subjoin the quantities of chloride of silver in relation to the solvent proportions of salt and water, as found by experiments; temperature 15° to 17° C.:—

Soluble Chloride of Silver. Milligrammes.	Nitrate of Soda. Grammes.	Water. Cubic centimetres.
1.33	0.787	100
1.93	0.787	200
3.99	2.361	300
2.53	2.787	100

The first of the above series of figures also refers to the quantities of chloride of silver, which may be precipitated by either solution of chloride of sodium, or nitrate of silver, both in equivalent proportions to each other, and therefore also equivalent with the chloride of silver of the first column, from liquids of the same composition as referred to in the second and third columns above mentioned.

The solubility of chloride of silver in nitrate of soda is no more to be relied on as soon as the chloride of silver has been discoloured by the light, for then there has been set at liberty some chlorine; hence the quantity of silver required is larger than what is equivalent to the last-added quantity of salt; while, secondly, the solubility of that chloride of silver which turned violet is greatly decreased. In the liquid obtained by dissolving one gramme of pure silver, to which precisely enough solution of salt had been added, in order to be brought to the neutral point, I observed, after twenty-four hours, when the chloride of silver had become pretty violet, that 0.575 milligrammes of silver solution were required to neutralise the chlorine set free; while I also found that the quantities of decimal solution of silver and salt which are required to precipitate each other mutually at 17° C. to the utmost limit, decrease from 20 drops or 1 cubic centimetre, to 13 drops, or 0.65 cubic centimetre.

I do not doubt a single moment that chloride of silver (provided it be first decomposed by light as much as possible) is insoluble in nitrate of soda. The remarkable phenomenon bearing upon the assay of silver just brought under notice deserves to be considered also from other points of view.

(To be continued.)

TECHNICAL CHEMISTRY.

On the Carburation of Gas.

THE following Report has been addressed to the Commissioners of Sewers of the City of London, by their Engineer, Mr. W. Haywood :—

"In pursuance of the resolution of the Court of the 23rd April last, I have directed an experiment with the view of testing the value of the application to the public lamps, of the process patented by the United Kingdom Carburing Gas Company.

"The patent of this Company is for placing near to the gas burners a receptacle containing coal naphtha, the gas passing through or over this takes up, and becomes enriched by the addition of the volatile hydrocarbons contained in the naphtha, and the illuminating power of the gas is thereby increased; the quality of the naphtha employed determines mainly the degree of illuminating power gained, and the chemical and photometrical experiments laid before me show that it varies from 25 per cent, to 77 per cent. (See Appendix.)

"The experiment being one in which the Gas Companies are much interested, I applied to the Chartered Company, who light Moorgate Street, suggesting their co-operation in conducting it with me; the suggestion was at once acceded to, and their Inspector, Mr. Johnson, was placed in communication with me for that purpose.

"Moorgate Street was selected as well adapted for the experiment, there being an equal number of lamps upon each side of the way, but one or two private lamps only in the street, and but few shops; the street is, therefore, after an early hour of the evening almost entirely without artificial light, excepting that which it derives from the public gaslights.

"The patentees stating that by the application of their process equal light would be given with half the ordinary consumption of gas, the burners were regulated accordingly.

"The lamps experimented upon were twelve in number, six upon the western side, which were fitted with the ordinary batwing burners, calculated to consume upon the average of the night 5 cubic feet of gas per hour, and six upon the eastern side, fitted with batwing burners, calculated to consume $2\frac{1}{2}$ cubic feet per hour. The latter burners having attached to them the carburing apparatus of the Company, each of the twelve burners had a meter attached to it, to ascertain the actual consumption. No pressure regulators were fixed upon the lamps.

"The registration commenced upon the 19th of June, and terminated upon the 19th of July inst., the experiment extending therefore over thirty nights, and gave the following results.

"That the burners without the carburing apparatus consumed about 4.39 cubic feet per hour.

"That the burners fitted up with the carburing apparatus consumed 2.09 cubic feet per hour.

"No photometer was employed, the equalisation of the amount of light given by the two classes of burners was a matter of judgment. The District Inspector of the Commission, who saw the lights nightly, reports his opinion that the light given was perfectly equal, and that his opinion is strengthened by collecting those of certain residents in the neighbourhood. My own opinion is that the light of the $2\frac{1}{2}$ feet burners was upon the average of the month inferior, although but very

slightly so, to that of the 5 feet burners. The Inspector of the Chartered Company coincides with me in this.

"No chemical analysis was made of the naphtha used; but it is stated by the patentees to have been of the best quality.

"My deduction from the experiment is, that with naphtha of equal quality to that used, that during the warm months of the year 3 cubic feet of carburated gas may be considered as about equal to 5 cubic feet of gas not carburated.

"Assuming this to be data applicable to all seasons of the year, I have estimated the saving to be effected by the process, and, after allowing for the cost of the apparatus, and for periodically filling it with naphtha, and, after giving credit at the present price of the gas supplied to the public lamps for the quantity not consumed, it shows that the reduction in the cost of each public lamp will be at least 1*l.* per annum; and there being 2825 lamps within the City, that a saving of 2825*l.* would be annually effected.

"The only disadvantage observed during the experiment was that the reservoir, as constructed, throws a disk of shadow round the base of the gas lamp standard, but the depth of shadow is but slight; this disadvantage may be largely rectified by an alteration in the form of apparatus.

"It should be understood that I do not pledge myself to any of these figures as exact, for the experiment as conducted cannot lay claim to be considered minute or exact in its character; but I believe it may, nevertheless, be taken as giving a close approximation to the truth; it is the mean of the rough results of practice, and the refined processes of the laboratory from which reliable data are generally drawn; in this case the results of the experiment are supported by laboratory experiments, and consequently there seems but little doubt that this mode of applying naphtha to the public lights (for the naphthalisation of gas itself is by no means new) may lead to a considerable reduction in the cost of public lighting; but what that reduction ultimately would be, would depend upon points which can only be determined by the application of the process to a considerable number of lamps for some length of time, and at different seasons."

The following is Dr. Letheby's Appendix to the above Report :—

"The apparatus consists of a chamber for holding coal naphtha, and of a contrivance for directing the stream of gas over the surface of the naphtha. By this means the gas becomes charged with volatile hydrocarbons, and acquires a higher illuminating power.

"Three sets of experiments were made for the purpose of determining the value of the apparatus. In the first set a naphtha rich in benzole was employed, and the results were, that at first it raised the illuminating power of ordinary twelve-candle gas to twenty-four candles, and in the course of three days the power fell to eighteen candles, the mean of the whole being twenty-one candles. This is an increase of 77 per cent., and it was effected by giving 10.77 grains of naphtha to each cubic foot of gas.

"In both of the other sets of experiments an inferior kind of naphtha was used, and in one case the average increase of illuminating power, during a period of ten days, and after the passage of a thousand cubic feet of gas, was 25 per cent. In the other case, after a duration of five days, the average increase was 30 per cent. The former was effected by the addition of four grains of

naphtha vapour to each cubic foot of gas, and the latter by 6.56 grains.

"These data are sufficient to indicate the general capabilities of the apparatus; for they show that with a good naphtha, supplied in proper quantity, and furnishing from ten to eleven grains of vapour to each cubic foot of gas, the illuminating power of an inferior gas may be nearly doubled. A less volatile naphtha, giving only from four to seven grains of vapour per cubic foot, will increase the power of twelve-candle gas from 25 to 30 per cent. I am, therefore, of opinion, that the apparatus is of practical value as a carburetting agent, and that if supplied with good naphtha, in proper quantity, there will be no difficulty in sustaining a power of twenty candles with ordinary coal gas."

Upon receiving this Report and Appendix, the Commissioners of Sewers resolved that it should be referred to the Engineer and Medical Officer of Health, to consider the conditions of the contracts for public lighting; having special reference to the increased illuminating power of the gas to be supplied, and to the possibility of carburing the gas by the process of the Carburing Company.

These gentlemen, Dr. Letheby and Mr. Haywood, have now reported upon this subject in the following terms:—

"Before considering the general conditions of a contract, it is necessary firstly to obtain the determination of your honourable Board to the leading principles upon which the contract should be framed, and it is to those we now specially address ourselves.

"As regards that portion of the reference which relates to the possible reduction of the consumption of gas in the street lamps, we are of opinion that, if the carburing process is not applied, the increase of the illuminating power proposed by the Metropolis Gas Act of 1861, does not render it expedient to diminish the amount of gas to be supplied at the burners of the public lamps; and that the contract should therefore remain as heretofore in this respect, unless the Companies alter the quality of the present supply, and furnish Cannel gas to the public lamps, as the Act of Parliament empowers them to do: under which circumstances it will be necessary to readjust the contract and mode of supply accordingly.

"With regard to the carburing process, we are of opinion, from the data obtained by the laboratory experiments quoted in the report to the Commission of the 30th July last, and the experiments made on the public lamps in Moorgate Street, during the months of June and July last, that the process of carburation appears to be capable of economising the use of gas in the public lamps, to the extent of from 40 to 50 per cent. This conclusion is founded on the assumption that the best quality of naphtha is to be used, namely, a naphtha which will give to the gas continuously a proportion of about ten grains of volatile hydrocarbon to each cubic foot of gas: these being the average results of the laboratory experiments. If an inferior kind of naphtha be employed, the results will be less satisfactory; for the laboratory experiments show that a naphtha yielding four grains of volatile hydrocarbon will increase the illuminating power of the gas to only about from 15 to 20 per cent.

"It is manifest, therefore, that the practical efficacy of these results will be entirely dependent on the perfection of the apparatus and the quality of the naphtha,

and we are of opinion that these essential conditions can only be secured during the earlier application of the process by an arrangement with the Carburing Company for the supply of the apparatus and the naphtha, as also for the maintenance of the same in complete working order, according to the terms of a contract founded on the preceding data, namely, that a burner consuming three feet of the naphthalised gas per hour shall give continuously the light of a burner consuming five feet per hour of the same gas not naphthalised; and to secure this, the naphtha should be of such quality as to furnish continuously not less than seven grains of volatile hydrocarbon to each cubic foot of the gas. If the Company is willing to undertake such a contract upon suitable terms, we see no difficulty in the practical application of the system.

"If these suggestions are adopted, it will be necessary to contract both with the Gas Companies and the Carburing Company; the terms of such contracts, which should have due relation to each other, must be a matter for future consideration."

PHARMACY, TOXICOLOGY, &c.

On Kerosolene, by EDWARD PARRISH.

SOME of the most useful scientific and practical discoveries have originated in accidents, the first results of which have involved disappointment or inconvenience. To evolve from these the lessons by which they may be made to subserve useful ends should be one of the chief aims of the experimentalist.

To the accidental anæsthetic effects produced upon a workman employed to clean a cistern in a kerosene oil works in Boston we owe the recent discovery of a new use for an abundant product of the destructive distillation of coal. This product, though heretofore procured in a crude condition at a certain stage of the process, in the works alluded to and perhaps in others, has not until recently been rectified and thrown into the market, because no demand existed for it for any known use of which it was capable.

With the enterprise so characteristic of New England character—a trait which so happily gave to science and humanity one of the greatest blessings of modern times—ether as an anæsthetic—the Boston physicians have taken measures to investigate the utility of this article for similar purposes, pending which it naturally claims the attention of pharmacutists in its physical and chemical characters.

Two bottles of the liquid have been sent me, the first by a medical friend residing in Massachusetts, and the second, at my request, by the manufacturer, Joshua Merrill, superintendent of the Downer Kerosene Oil Company, from whom I learn that kerosolene, as it is named, is a product of the destructive distillation of "Albert coal," at temperatures varying from 600° to 890° F. The very volatile portion, separated by careful fractional distillation from the more fixed products which are sold as kerosene, is purified so as to remove its unpleasant odour, and thoroughly rectified.

As thus produced, kerosolene is a tasteless, colourless, though highly refractive, inflammable liquid, burning with a bright smoky flame. It is very mobile and volatile, and the bead disappears immediately. A vial, when grasped by the palm of the hand, gives off small bubbles of vapour, raising the stopper. Its odour is very faint, reminding of chloroform at first, though less

agreeable as it evaporates, leaving not the slightest odour when it dries. Its sp. gr. varied in the two specimens at first received, that of No. 1 being .6346 at 76° F., of No. 2 .6325 at 72° F.; but by exposure for two weeks in a partly filled tincture bottle, occasionally opened, the specimen marked No. 1 reached a sp. gr. of .6420 at 72° F.

From the last named fact and its known origin and mode of preparation, it would be supposed that this liquid had not a uniform composition, but must be a mixture of different carbohydrogens of varying density and volatility. The truth of this was proved by the following experiments:—Specimen No. 1 was heated in a water bath, and its boiling points carefully noted. At 84° F. it commenced to boil, the temperature rapidly rising to 90°, and afterwards slowly, without becoming stationary, to 150°, when boiling ceased, about one-sixth of the original liquid remaining, which was evaporated at about 200° without boiling. Specimen No. 2 was subjected to similar experiments. It commenced to boil at 82° F., ceased at 94°, recommenced at 100°, and ceased at 105°, when the remainder, about two-thirds, was evaporated without boiling, at a temperature not exceeding 180°.

The extremely low sp. gr. of this substance and the temperature at which it begins to boil forbid the idea of its containing the ordinary coal tar products in considerable proportion. The light naphtha first obtained in the distillation of coal tar has a sp. gr., according to Mansfield, of .900 to .950, and when purified by agitation with sulphuric acid and potash, or by the process of Gregory, in which peroxide of manganese is used, and rectified, its density does not fall below that of benzene, the sp. gr. of which, in its liquid form, is variously stated at .85 and .8991, at different temperatures.

The largest proportion of kerosolene is evidently composed of those very light carbohydrogens not present in coal tar, and not produced at the high temperatures employed in the production of illuminating gas.

In the books I have consulted I find no detailed account of these almost gaseous liquids, and I can imagine no subject presenting more difficulties to the chemist. Professor Antisell, in his thoroughly practical work on Photogenic and Hydrocarbon Oils, remarks that "the specific gravity and chemical constitution of the light and heavy oils vary in relation to the temperature at which they are distilled; and perhaps no two distillations give exactly the same relative mixture of the various hydrocarbons of which they are composed." The composition of these is further varied by the nature of the crude materials, which may be highly bituminous, like the "Albert coal," from which the specimens under consideration were obtained, or more completely formed coals like the more common varieties.

The proportion of matter volatile at redness in the "Albert coal" has been stated at 61.74 per cent., that of the "Breckenridge coal," of Kentucky, at 60.27 per cent., while Pittsburg coal yields but 32.95 per cent.

Chemists have obtained from coal tar by fractional distillation several substances of great utility. Of these benzene or benzol C_6H_6 , which, as before stated, is the chief constituent of the light naphtha, is also a constituent of kerosolene, as ascertained by testing it with nitric acid, which developed the odour of nitrobenzol. The chief constituents of the photogenic liquids as thrown into commerce under the name of coal oils or kerosolene, are toluol C_7H_8 , which has a sp. gr. of .870 and boiling point 237° F. (Gerhardt 230), and Cumol $C_{10}H_{12}$, which is also lighter than water, and boils at 314°. It is not

improbable that traces of these may be present in the new liquid, though they vary from it so much both in sp. gr. and boiling point. Experiments to detect aniline C_6H_5N in the specimens under examination failed to indicate it as might be anticipated, its sp. gr. being stated at 1.020, and the process of rectification with sulphuric acid being adapted to separate any alkaloids if originally present.

Compared with the commercial article of benzol, now so extensively sold, kerosolene presents several marked points of difference. Three specimens of benzol I have examined have respectively, at 60° F., the sp. gr. .7521, .7661, and .8708. These differ in sensible properties from each other almost as much as they do from kerosolene. The most agreeable in odour I imported from England at a much higher price than that paid for the American varieties, which I have generally found disagreeably "balsamic," sometimes resembling impure illuminating gas, and leading to the belief that the gas was escaping into the room. One specimen became almost intolerable by age, while the colour became gradually yellow. Kerosolene, as before stated, is almost free from odour; it is so very mobile, light, and colourless that it could not be mistaken for benzol, and still less for kerosene, its properties having relation to the latter substance not unlike those of ether to oil of turpentine.

Under the name of Eupion chemists formerly described a product of the destructive distillation of wood, which was believed to be C_8H_{10} , but it has since been shown by Voelekel that the portions rising below 212° F. consisted chiefly of acetate of methyl with acetone, a little benzol, xylite, and mesite.

The sp. gr. of eupion was stated at .655, its boiling point at 113° F., rising as high as 336° in some samples. Though stated to be the lightest of known substances, it will be seen that this product was rather more dense than our new carbohydrogen product. Accounts differed in regard to its miscibility with water and alcohol. It was, however, described as freely miscible with ether and oils, and as being of a faint and agreeable odour and without taste, which properties correspond with those of the liquor under consideration. That kerosolene contains no more than a slight trace of any oxygenated body was shown by immersing sodium in it, a fresh surface of the metal was only slightly tarnished by the contact.

The solvent properties of this new substance are of course of primary importance. They appear to me to present the true key to its usefulness. It dissolves fixed oils, apparently, in all proportions, common resin freely, though with flocculent residue, wax and cocoa-butter freely, mastic and caoutchouc slightly. It mixes freely with alcohol, oil of turpentine, ether, and chloroform, but not with water. Iodine dissolves in it sparingly, yielding a remarkably rich, though changing, purple colour.

For the common uses to which benzol is now applied, kerosolene appears to be equally adapted. By the absence of disagreeable odour it is rendered generally preferable. It is, however, unsuited to the purposes of illumination, or to generating heat, being too volatile, though its vapour does not appear to be explosive. Its extreme volatility makes it important that it should be excluded from the kerosene or other photogenic oils, and renders it a residuary product, heretofore without value, of those works in which it has been produced in a crude condition.

How far this product could be furnished by the manu-

facturers, of uniform quality, or whether it could be produced at other kerosene works, and by those numerous establishments in which the so-called rock oils now pumped in such vast quantities in the western slopes of the Alleghanies, are rectified, is a practical question yet to be tested. Its relations are evidently to this class of bitumens rather than to coal tar.

In view of its use in medicine, the fact of the great uncertainty of its composition, its being a mixture of different and undetermined proximate constituents, must interfere with its general adoption and recognition.—*American Journal of Pharmacy.*

*On the Preparation of a Natural Iodine Wine,
by Dr. BOINET.*

ORIGINALLY administered in the natural state and dissolved in water by Coindet, iodine has been exhibited much more efficaciously through the intervention of iodide of potassium, as recommended by Dr. Lugol. This latter salt, indeed, has been almost completely substituted for it, and it is nearly exclusively in this form that internal treatment with iodine is effected.

Reason, however, points out that advantage is gained in giving medicaments in a state as nearly as possible like that in which they are found in nature; and, indeed, iodide of potassium, on account of the special action which it exerts on the mucous membranes of the eye, nose, and larynx, offers real inconveniences, and is impossible to be taken by some persons.

Under these circumstances, M. Debauche has opened a way which promises to be of service in showing how to render iodine soluble in tannin without the aid of iodide of potassium. From this has arisen M. Boinet's idea of administering iodine in liquids or syrups containing tannic acid, such as the wines of horse-radish, quinine, gentian, walnut, or orange peel.

Arguing upon the good results effected by iodine contained in mineral waters, certain salts and plants, and burnt sponge, although these only contain very small quantities, remembering the results which he had already obtained by the incorporation of this metalloid into articles of food (iodised alimentation); and, as he has repeatedly said, to get farther from the laboratory and nearer to nature, M. Boinet has been induced to search for a preparation of this kind which would not have upon the tongue, the throat, nor the stomach, the ill effects of ordinary iodine wines, which are usually prepared by the addition of tincture of iodine or iodine of potassium. This is what he does:—

At the time of vintage commence by picking the grapes so as only to have them ripe and fit to make good wine. They must not be picked off the bunch, on account of the tannin and salts contained by the stalk, which serve to preserve the wine and aid fermentation. They are placed in a large wooden tub capable of holding many barrels of wine. At the bottom is placed a thick layer of grapes, then above a layer of powdered seaweed, or even a layer of ashes of these plants; then a fresh layer of grapes, then another layer of sea-weed, and so on, until the tub is full. The whole is then covered with a layer of chopped straw to keep the air away and favour fermentation. The important operation of working now commences, which lasts from fifteen to twenty days, according to the temperature. When the wine is fit to draw off—that is to say, when the fermentation is complete and the grape sugar changed into alcohol and carbonic acid, and it has dissolved and

assimilated to itself the iodine contained in the weeds—it is placed in casks, keeping it as much as possible from contact with the air. To effect this, it must be drawn from the tub by means of a tap. The concluding operations are effected as with ordinary wine. This wine is, however, nothing more than a tincture of iodine, obtained like other tinctures, as that of aloes, opium, &c., by maceration and fermentation.

This wine M. Boinet calls natural iodine wine. It keeps as well as ordinary wine, and has not, like syrups, the inconvenience of fermenting and decomposing. It contains so much iodine that it can even be mixed with other wine before being administered. The dose may be two or three spoonfuls unmixed per day for adults, and the same in coffee for children. M. Boinet usually administers it in the following manner:—In the wine usually drank at meals; or in any other beverage, a spoonful of this iodine wine is mixed at each meal. This wine has no disagreeable taste, and were invalids not told of it, they would not suspect that they were taking iodine or wine containing iodine.—*Bull. de Thérap.*

PHYSICAL SCIENCE.

On Spectrum Analysis, by M. MORREN. (Extract from a letter to the Abbé Moigno, Editor of "Cosmos.")

WHILST I fully appreciate the beautiful researches of M.M. Bunsen and Kirchhoff, I cannot but feel that their conclusions in respect to the constitution of the solar photosphere are somewhat premature and hasty. I will, in the first place, state that the yellow ray D, which is used as an argument in favour of admitting sodium as a constituent of the photosphere will prove as much for many other bodies. I might name several, but will confine myself to iron and mercury. This latter metal gives the yellow ray D, double and in a marvellous manner, together with the most beautiful violet ray that can be imagined. Another thing which ought to make us speak with extreme reserve is, that we have as yet only very incomplete knowledge of the spectra of metals. Some eminent physicists (I mention those quoted by the Heidelberg savans), M.M. Van der Willigen, Masson, and Angström, have only seen an inconsiderable number of rays belonging to many metals, especially iron; and this may be perfectly imagined at the present time, for, indeed, in the voltaic arc produced by the battery many parts must be distinguished.

1. An incandescent, very luminous portion formed of the electrodes, of dazzling lustre if they are of carbon, and fused if they are metallic. This portion only furnishes a very brilliant, continuous spectrum, free from lines.

2. The gaseous aureola, which in a powerful battery is very large, and which alone yields rays. This aureola, when the electrodes are of carbon, is formed, as is known, of two oval, concentric parts, the one violet in the centre, and the other orange throughout. It is reasonable to suppose that each of these has its distinct lines, and that the surrounding medium may also play some part in it. It is, moreover, certain that those physicists who, for want of a sufficiently powerful battery, have experimented with the electrodes too near together, have only been able to see a very limited number of brilliant rays; being overpowered by the presence of the continuous spectrum, dazzling and free from rays, formed by the incandescent liquid or solid portion of the electrodes. Hence all these differences. This week I have been

working with a battery of 65 Bunsen's elements, large size, and I have obtained with iron an admirable aureola, in each part of which, even in a very small space, the rays were in excessive number. With a powerful magnifying apparatus, I have seen skilful persons unable to count them in the field of the telescope without great difficulty. In the presence of rays so close together and so little known, it is difficult to establish without error unexceptionable coincidences.

I think, therefore, that before affirming that such or such a metal produced the negative spectrum of the sun by its presence in the photosphere, we should be perfectly acquainted with the spectra of metals, gases, and all bodies; whereas we have at present but the rough outline of such a work which is called for by the state of science. It is to be desired that these important spectra should be made with extreme care, under the control of the several savans who have studied this branch of physics, and especially under perfect and comparable conditions. Having drawn such spectra, I know how delicate and difficult is such a work; the most skilful at it are liable to error. For instance, I will mention to MM. Bunsen and Kirchhoff the extreme red ray of potassium. These gentlemen have said that it exactly corresponds to the solar line A. That is not so. The red ray of potassium is remarkable in that it is so much less refrangible than the line A of the solar spectrum that it is difficult to see, when no other precautions are taken to see it than those which suffice to illuminate and show in their beauty all the red rays of solar light. Owing to the length of this letter, I must defer entering upon details until another occasion. The red ray of potassium is at this moment the least refrangible ray of light known. I have, besides, made this experiment for the first time in the presence of M. Plucker. We first placed the micrometer wire over the solar line A; then, without touching the apparatus we observed in it the red ray of potassium. Having measured this, we returned once more to the ray A. The difference of minimum deviation between these two rays is at least 20'.

P.S.—Later researches enable me to state that the blue part of the flame of the candle, alcohol, lighting gas, paper, &c., is due to the combustion of *proto-carburetted hydrogen*, and not of *oxide of carbon*, as has been hitherto supposed, and as I myself have stated before. Spectral analysis proves this in an incontestible manner.

*On the Blue Band of the Lithium Spectrum,¹
by Professor FRANKLAND, F.R.S.*

ON throwing the spectrum of lithium upon the screen yesterday I was surprised to see a magnificent blue band. At first I thought the chloride of lithium must be adulterated with strontium, but on testing it with Steinheil's apparatus it yielded normal results without any trace of blue band. I am just now reading the report of your discourse in the CHEMICAL NEWS, and I find that you have noticed the same thing. Whence does this blue line arise? Does it really belong to the lithium, or are the coke points or ignited air guilty of its production? I find three blue bands with chloride of sodium, but they have not the definiteness and brilliancy of the lithium band. When lithium wire burns in the air it emits a splendid crimson light; plunge it into oxygen

and the light changes to bluish-white. This seems to indicate that a high temperature is necessary to bring out the blue ray.

P.S.—I have just made some further experiments on the lithium spectrum, and they conclusively prove that the appearance of the blue line entirely depends upon temperature. The spectrum of chloride of lithium ignited in a Bunsen's burner-flame does not disclose the faintest trace of the blue line. Replace the Bunsen's burner by a jet of hydrogen—the temperature of which is higher than that of the Bunsen's burner—and the blue line appears, faint, it is true, but sharp and quite unmistakable. If oxygen be now slowly turned into the jet, the brilliancy of the blue line increases until the temperature of the flame rises high enough to fuse the platinum, and thus puts an end to the experiment.

Note by Dr. Tyndall.

[On the occasion referred to by Dr. Frankland, it was a general impression among the chemists present at the lecture that I had used the word lithium for strontium throughout the evening. This induced me to ask Dr. Miller to test my chloride of lithium, which he found quite pure. I afterwards showed the blue band, the splendour of which is unrivalled, to my class at the School of Mines. The coal points without the lithium show nothing of the kind; with the lithium the band always appears. Either, therefore, the substance itself is so altered by the exalted temperature that new periods of oscillation are possible to it, or the medium in which it vibrates is so changed in elasticity as to permit of the same thing. The observation appears to be one of considerable significance. I would also draw attention to the experiment by which the absorption of the yellow band by the sodium flame was effected on the same occasion as one of the most striking class experiments in the whole range of optics. It is very easily performed, a band 18 inches long and three-quarters of an inch wide being quite attainable within ordinary lecture-room limits. A salt flame 10 feet thick produced no such effect. Dr. Miller, I am informed, repeated this experiment with success before an evening meeting of the British Association at Manchester.]

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY OF DUBLIN.

Monday, November 25, 1861.

The Honourable J. P. VEEKER, F.R.S., President,
in the Chair.

The minutes of the former meeting having been read and confirmed, the PRESIDENT called on Professor C. A. Cameron, M.D., M.R.I.A., to deliver a discourse "On Bunsen and Kirchhoff's Method of Spectrum Analysis."

Dr. CAMERON commenced by observing that he was induced to bring the subject before the Society by the consideration that it has not, up to the present time, been brought publicly under the notice of any of the learned Societies in Ireland, although this has frequently been done on the other side of the Channel. He then made some observations on the nature of light, and the mode of forming the solar prismatic spectrum. He pointed out the dark spaces termed "Fraunhofer's lines" in the spectrum, and demonstrated the coincidence of these with the luminous bands observable in the spectra of certain of the metals, and, likewise, how they were caused by what might be termed a negative spectrum of the luminous envelope of the sun. He then exhibited the spectra

¹ In a letter from Professor Frankland to Dr. Tyndall, published in the last number of the *Philosophical Magazine*.

produced by burning salts of sodium, potassium, calcium, &c., and explained the method of using the spectroscope, which, in this instance, was the form of apparatus described by Mr. Crookes, and supplied by Spencer Browning and Co. Dr. Cameron showed that, by means of this instrument, the presence of inconceivably small quantities could be easily and expeditiously detected. Thus it was found that soda was almost always present in the atmosphere, and that the metal lithium, hitherto supposed to be found only in a few rare minerals, such as Killinite (found at Killiney Hill), was universally diffused; and also, by its means, three new elementary bodies have been discovered, two by MM. Bünsen and Kirchhoff, and one by Mr. Crookes. The discourse was illustrated by diagrams and numerous experiments, and at its close there was warm applause.

A paper was then read by Mr. EMERSON REYNOLDS, Assistant-Chemist to the Society, "*On a New Process for Photographic Printing.*" The author commenced by apologising for bringing a photographic subject before the Society at all. He said that he would not have done so, only that his process was intimately connected with a subject which he would have the honour of communicating at the next meeting of the Society. Mr. Reynolds then went on to say that in the early part of last year accident had led him to the study of some of the compounds of oxalic acid with the oxides of iron, and, while pursuing his investigations, he had observed a peculiar decomposition to take place under the influence of the solar rays,—namely, the reduction of the peroxalate of iron to the state of protoxalate. At first he was under the impression that no one had noticed this fact before, but subsequently he ascertained that Dobereiner had pointed it out in the earlier part of the present century, however, no one thought of applying the reaction to photographic use. This he has done, and has been very successful in working out the subject. His process is substantially as follows:—Paper is saturated with a solution of ammonio ferric oxalate in the usual way, when dried in the dark, it is exposed under a negative, and after being sufficiently printed, is taken out of the pressure frame and thoroughly washed with water. The picture, which is now of a light yellow colour, is then immersed in a very dilute solution of ammonio-nitrate of silver, containing as little ammonia as possible, when it is immediately developed, and appears of a fine dark colour, all that now remains to be done, is to wash, dry, and mount, when the picture is finished. The author states that the whole process from the commencement of the printing till the picture is mounted, on a fine day, does not occupy more than two hours, in this time he has obtained pictures, which up to the present, have not faded in the least. Several specimens of the process were shown and were much admired by those present.

Mr. CHARLES R. C. TICHBORNE then read a paper "*On the Naphthalene Colours.*" This paper is supplementary to one, by the same author, which appeared in a late number of the CHEMICAL NEWS. Mr. Tichborne did not confine himself to his own experiments, but gave a general and very lucid description of the various products of the destructive distillation of coal. He explained the means which are adopted for purifying the crude naphthalene, and exhibited some beautifully crystallized specimens. He then proceeded to notice M. Roussin's paper on artificial alizarine, and produced some of that colouring matter by the action of a reducing agent on the binitro-naphthalene, and directed particular attention to the precautions to be observed so as to obtain the largest yield of the dye. The author then went on to say that it is from madder we get the colours known as Adrianople or Turkey red, which is the most durable vegetable tint known. The discovery is traceable to India. The process was afterwards practised in Asia and Greece, and, about the middle of the last century, works were established

near Rouen. In 1765 the French Government caused an account of it to be published. Its introduction into England, at the end of the eighteenth century, was by a Manchester house, but the proper method of treating it was made known by a Frenchman (Papillon), who brought it into Glasgow. This latter town is still celebrated for this class of dyeing. Mr. Tichborne then went on to show the very close connexion which exists as regards physical and chemical properties between alizarine—the most important tinctorial principle of madder—and the colouring matter produced by the action of reducing agents on binitro-naphthalene, although their identity in chemical constitution was not proved; for, as yet, no analyses have been made of the dye. Attention was then directed to the formation of a blue colour by means of cyanide of potassium, which the author has found may be converted into a beautiful green tint by the addition of some di-nitraniline. Dinitraphenic acid and the other yellow tar-products are not applicable. He concluded by exhibiting a number of specimens of ribbon and woollen fabrics which he had dyed with these colours, and are likely to prove most formidable rivals to the aniline compounds.

ROYAL INSTITUTION OF GREAT BRITAIN.

General Monthly Meeting, Monday, December 2, 1861.

WILLIAM POLE, Esq., M.A., F.R.S., Treasurer and Vice-President, in the Chair.

James Bass, Esq., Rev. George Bowes Macilwain, B.A., and David Ricardo, Esq., were elected Members of the Royal Institution.

NOTICES OF BOOKS.

A Manual of Chemistry, Descriptive and Theoretical. By WILLIAM ODLING, M.B., F.R.S. Part I. London: Longman and Co. 1861.

THIRD NOTICE.

AMONG carbon compounds we may cite the following as examples of heterologous series, taking the homologous methylene and ethylene as starting-points:—

Methylene . .	CH ₂ .	Ethylene . .	C ₂ H ₄ .
Formic aldehyde	CH ₂ O.	Aldehyde . .	C ₂ H ₃ O.
Formic acid . .	CH ₂ O ₂ .	Acetic acid . .	C ₂ H ₃ O ₂ .

Professor Odling makes frequent use throughout the volume of tabular statements, which present at once, to any one capable of reading chemical formulæ, the clearest view of the relations between the bodies cited, and express in a few lines what would require a page or more to explain in words. Not only do these tables include numerous examples of homologous, isologous, and heterologous series, but our author arranges in like manner the various combinations of the same radicle. The following illustration refers to peroxide of hydrogen, the eurythane of Laurent:—

"The compound radicle, peroxide of hydrogen, H₂O₂, is equivalent to the simple radicle, chlorine, Cl, and in a great number of reactions is exchangeable for chlorine and its congeners. One of the most generally useful modes of oxygenating different compounds consists in first substituting a halogen in exchange for hydrogen, and then, by means of water, substituting peroxide of hydrogen in exchange for the halogen. Thus, by the action of bromine upon acetic acid, we obtain bromoacetic acid :

Then by the action of water upon bromoacetic acid we obtain glycolic or oxyacetic acid :

It is observable that water may be regarded as a derivative of chlorhydric acid, in which the compound radicle HO replaces the simple radicle Cl, and so in other instances, thus :

Chlorhydric acid	H.Cl	H.HO	Water
Chlorine	Cl.Cl	HO.HO	Perox. of hyd.
Chloride of ethyle	C ₂ H ₅ .Cl	C ₂ H ₅ .HO	Alcohol
Chld. of benzoyle	C ₆ H ₅ O.Cl	C ₆ H ₅ O.HO	Benzoic acid
Chld. of sulphuryl	SO ₂ .Cl ₂	SO ₂ .(HO) ₂	Sulphuric acid
Chld. of phosphoryl	PO ₂ .Cl ₃	PO ₂ .(HO) ₃	Phos. acid."

An excellent table of the sulphates, showing the anhydrous sulphates and those containing various amounts of water of crystallization, will be found on page 176.

In the accounts of the oxides and hydrates, which is altogether thoroughly well-written and full of interesting matter, the reader will find the classification of the peroxides, and the relations of the oxides to the hydrates and the acids described with greater completeness than elsewhere.

The author has avoided a fault into which some advocates of the Unitary Notation repeatedly fall. It is very well to insist on the fact that formulæ do not necessarily indicate the constitution or building up of the substances to which they have been assigned, but that they chiefly serve to show the atomic relations of the constituent elements; yet the connection of one compound with another is lost sight of by the student whose teacher ignores compound radicles, and jots down before his class the formula of sulphuric acid sometimes as H₂SO₄, sometimes as 8H₂O₄, and occasionally goes so far as to break it up, in a playful but not instructive manner, into as many pieces as possible. Those who have just liberated themselves from the traditions of the older chemical theories, should take care that their very liberality does not degenerate into dogmatism, for it must not be affirmed that the Unitary System is itself already perfect, and cannot admit of further development.

Dr. Odling discourses with ease and confidence in these pages, and not infrequently with a clearness and force that are truly admirable. He has shown, in many directions, the advantages accruing from the new system; and it is with pleasure rather than disappointment, that we see how, here and there, he expresses a doubt about the correctness of some of the views which he holds. We cannot help feeling sorry that Professor Odling has banished so completely from the volume before us, the great chemists, the results of whose labours are there collected and arranged. The student should occasionally be reminded of the careful and exact Berzelius, the brilliant Davy, the sagacious Dalton, and a few other illustrious names. Even Laurent and Gerhardt, the author's immediate teachers, scarcely get due credit in the body of the work itself, and a young reader might come to the conclusion—a conclusion which Professor Odling would be the last to encourage—that the author himself was the chemist of chemists. We also miss a clear, compact account of the grounds on which the change of systems is based. But the author continually shows a peculiar power of appreciating the bearings and relations of chemical facts discovered by others, and the task which he has undertaken is one for which he is well fitted. We have derived so much pleasure from examining Part I. of this work, that we wait anxiously for Part II.

1706. Bevan George Sloper, Hackney, London, "An improved method of, and machinery for, amalgamating and for effecting the separation of gold from earthy and other matters containing the same."—Petition recorded July 4, 1861.

1732. Thomas Cogley, Meerholz, Hesse, Germany, "An improved process for the manufacture of fluo-silicates and silicates of lead and baryta, and for the application of the same to various purposes in the arts and manufactures."—Petitions recorded July 8, 1861.

1733. Thomas Telford Macneill, Cockspur Street, London, "Improvements in the construction of barometers, and in apparatus for registering the indications of the same."

1734. Thomas Cogley, Meerholz, Hesse, Germany, "An improved process for the treatment of silicates of metallic and non-metallic bases and other siliceous compounds of slags, scorix, and such like, in order to recover the said bases, and also in the production of fluo-silicic and silicic acids."

1756. Thomas John Smith, Queen Street, Cheapside, London, "Improvements in photographic albums."—Petition recorded July 12, 1861.

1772. Thomas Cogley, Meerholz, Hesse, Germany, "Improvements in the manufacture of metallic or earthy silicates or siliceous compounds of the same from the metallic and earthy bases or their salts and soluble alkaline

silicates, the formation of alkaline acetates or caustic alkalies, and application of the same."

1773. Thomas Cobley, Meerholz, Hesse, Germany, "An improved process for preserving indurated timber, wood, and other vegetable matters, and for rendering the same unflammable."

1776: Thomas Cobley, Meerholz, Hesse, Germany, "An improved process for the production or manufacture of fluo-silicates of tin, zinc, and baryta, and their application as pigments for glazing, enamelling, and in the manufacture of glass."—Petitions recorded July 15, 1861.

2110. Richard Archibald Brooman, Fleet Street, London, "An improved method of treating the hop plant to obtain a material resembling wool."—A communication from Barthélemy Picard, Nancy, France.—Petition recorded August 23, 1861.

CORRESPONDENCE.

Fixing Colouring Matters.

To the Editor of the CHEMICAL NEWS.

SIR,—I observe, in No. 103 of your useful Journal, Notices of Patents taken for Fixing the Colouring Derivatives of Tar on Vegetable Fabrics, by Messrs. Miller, of Springfield, Glasgow, and by several others, all of which embody a common principle of fixing those colours by the formation of a tannate of tin from an alkaline stannate, in the fabrics—if we except that of Lloyd and Dale's, and of Church, who substitute antimony for tin—still retain the same principle.

I feel called, in duty to myself, and it may be the case with other practical men, to say, that ever since the introduction of mauve by Perkins, and of roseine by Simpson, I have followed the above plan, with considerable success.

I am, &c.

JOHN HAMILTON.

Armitage Dye House, near Huddersfield.

Sparteine.

To the Editor of the CHEMICAL NEWS.

SIR,—Would you do me the favour of correcting an error in your last Number, contained in a report of the Proceedings of the Chemical Society? In a paper on Sparteine I am made to state that this base appears to be "homologous with nicotine." This was merely a suspicion, entertained prior to investigation,—at the end of which sparteine was found to be $C_{12}H_{26}N_2$. As nicotine is $C_{10}H_{14}N_2$, the bodies have, clearly, no relation of homology. The mistake is trifling enough in itself; but some of your readers might further imagine that it had been asserted in the original paper.—I am, &c.

EDMUND J. MILLS.

December 2.

On the Adulteration of Butter.

To the Editor of the CHEMICAL NEWS.

SIR,—It is not with any feelings of rivalry that I refer to the paper of Dr. Ballard in the last Number of the CHEMICAL NEWS, alluding to that of mine on the Adulteration of Butter, but, on a comparison of the two papers, it must be evident that the simplicity and practical utility of mine are not in the slightest degree diminished by the publication of the Doctor's.

Dr. Ballard takes objection to the ether process on the score of expense. This is a matter of assumption merely, a teaspoonful or so of ether being ample for an experiment. Surely that quantity is not so expensive as to condemn its utility. More than that, I had a particular object in view in writing my paper—to show, in answer to a Correspondent, how easily lard—for that was the question—may be detected; and then I thought I might as well

experiment on, and possibly include, other kinds of fat, which, I found, could all be readily identified thereby; but not so by the plan of Dr. Ballard, who considers "Beef Dripping" to be the general fatty adulterant used, which does not accord with my experience.—I am, &c.,

JOHN HORSLEY, F.C.S.

The Laboratory, Police Station, Cheltenham.

MISCELLANEOUS.

Gas from Water.—Arrangements are being made, it is understood, at the Leeds Gasworks for the manufacture of gas from water, much on the principle carried out, some years ago, by Mr. White, in Manchester. Steam is decomposed in passing over incandescent coke or charcoal, and the liberated hydrogen is afterwards carburated by being passed through resinous or other carbonising matter.—*Engineer.*

The Warmest and Best Clothing.—Most persons suppose that fabrics made of coarse wool are the warmest and most durable. This is a mistaken idea. Owing to the lower prices of coarse wool, fabrics of this material are usually made heavier than those of fine wool, hence their greater thickness deceive persons respecting their qualities for warmth and wear. There is no heat in the wool itself; its property of what is called "warmth" is due to its non-conducting qualities. If we grasp a bar of iron on a frosty morning it produces a disagreeable cold sensation because it is a good conductor of heat, and the warmth of the hand is rapidly carried off by the metal. On the other hand, a piece of woollen cloth, especially if it has a long nap upon it, does not feel cold because it is a good non-conductor, and prevents the heat passing rapidly from the hand. Now the warmest fabric for clothing is that which is the best non-conductor; and Count Rumford made a great number of experiments with different materials in order to find out the best. According to his observations, the down of the eider duck, which the Esquimaux use in their clothing, is unrivalled in this respect; and the finer the fabric of woollen cloth used, the more imperfectly did it conduct the heat from the human body. As fine woollen cloth is superior to that of coarse wool as a non-conductor, it is therefore the best for clothing in keeping the body warm during cold weather. We are also positive that cloth made of fine wool equal in thickness to that manufactured from the coarser material will wear much longer. The finest woollen cloth, although dearer at first, is cheapest in the end, because it is more durable and warmer; and according to Liebig, so much heat saved is so much meat gained. It must not be overlooked, however, that there may be a very great difference between what is called "firm cloth" and cloth made of fine wool. Fine wool is our theme; it feels pleasant and soft to the touch, and it has a rich velvety appearance. There has been a great demand recently for coarse wool to be used in the manufacture of common army and other cloth, but every effort should rather be made to obtain plenty of cheap fine wool, because it is the warmest and best for clothing.—*Scientific American.*

ANSWERS TO CORRESPONDENTS.

* * All Editorial Communications are to be addressed to the EDITOR; and Advertisements and Business Communications to the PUBLISHER at the Office, 1, Wine Office Court, Fleet Street, London, E.C.

J. Horsley.—We shall be pleased to receive the paper you speak of, at your convenience.

F. Harrison.—You will obtain better results by having forty Groves' cells of the ordinary size, than by using the same surface of platinum in four large cells. This would be an admirable "quantity" arrangement, but would be very deficient in "intensity," and for brilliant lecture experiments the latter is as necessary as the former. No addressed envelope arrived.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Researches on the Relations existing between Atomic Weights, by M. J. S. STAS, Member of the Royal Academy of Belgium.

(Continued from page 107.)

Synthesis of Nitrate and Sulphate of Lead.—Before explaining how I proceeded with the synthesis of nitrate and sulphate of lead, I ought to point out the means which I made use of to procure pure lead.

Preparation of Pure Lead.—The preparation of pure lead offers perhaps even more difficulty than that of pure silver. After a considerable number of trials, I had recourse to these methods to obtain the metal employed in my experiments. Commercial acetate of lead was dissolved in warm water, contained in a large leaden digester, and kept at a temperature of 40° to 50° in contact with very thin sheets of lead until all the copper and silver were precipitated. The solution was then filtered and poured into nearly boiling water, strongly acidulated with sulphuric acid. The sulphate of lead was washed by decantation until the washing waters contained no trace of sulphuric acid. The salt was then transformed into carbonate by means of a mixture of sesquicarbonate of ammonia and solution of ammonia; for this it is only needful to diffuse it in the water containing the alkaline salt, an effervescence takes place, which lasts as long as there remains sulphate of lead undecomposed. At this point I decant the solution of sulphate of ammonia and the excess of carbonate of ammonia, and wash it with pure water as long as the washing waters contain sulphate in solution.

The carbonate of lead thus formed dissolves entirely in dilute nitric acid. It is perfectly free from foreign metals, except traces of iron, which adhere to the sulphate of lead in spite of the excess of sulphuric acid employed. To separate the iron, I transformed a portion of this carbonate of lead into oxide, by heating it carefully in a platinum vessel. Another portion was dissolved in dilute nitric acid, taking the precaution to leave some of the carbonate undissolved. The solution of nitrate was heated to ebullition, and the oxide of lead was then gradually added to it. The oxide in dissolving precipitated traces of iron. The liquid was filtered and an excess of sesquicarbonate of ammonia poured into it. In the carbonate of lead thus obtained it has been impossible for me to discover the slightest trace of foreign metal. It is this carbonate which I have converted into metallic lead. To effect this, after having dried it, I project it, by small quantities at a time, into pure fused cyanide of potassium. As this reduction ought to be effected in a white, unglazed, porcelain crucible, which is very liable to break, I have had recourse to the same plan which I used in the reduction of silver from its chloride, and in the fusion of the pure metal,—that is to

say, I fixed the porcelain crucible in the centre of another larger one, interposing between them calcined pipe-clay, which had been reduced to powder, cementing the whole together by the addition of five per cent. of fused and powdered borax.

The lead obtained by the first operation is heated a second time with pure cyanide of potassium until it presents at the bottom of the cyanide a surface as convex and brilliant as pure mercury. When it is somewhat cool I cast it in a polished ingot-mould of cast steel.

When the lead contains the slightest trace of oxide or sulphide of this metal it does not present a convex surface when it is fused.

Pure lead is much whiter and more soft than the ordinary metal. It appears to tarnish very rapidly when exposed to the air.

Instead of reducing the carbonate of lead by cyanide of potassium, I have employed for this purpose the black flux obtained by carbonising purified Seignette salt. To entirely deprive this salt of foreign metals, I first pass a current of hydrosulphuric acid through its boiling solution; I then pour in a few drops of sulphide of sodium solution. The coloured solution, left to itself for fifteen days in a well-stoppered bottle, becomes completely decolorised by depositing the metallic sulphides. The decanted solution is agitated with tartrate of lead as long as it contains the slightest trace of sulphide of sodium. Before calcining the Seignette salt, I always test it to see that it contains neither sulphide, sulphate, nor foreign metals.

The carbonate of lead mixed with the pulverised black flux is reduced by the action of heat. The temperature necessary for the fusion of the alkali being tolerably high, there are almost always a certain quantity of alkaline metals reduced, which alloy with the lead. To remove these metals, I heat the lead for some time in contact with the air, continually stirring the metallic bath with a rod of pipe-clay. When I have thus oxidised a certain quantity of the lead, I pour on the mass fused cyanide of potassium, and heat the whole until a great portion of the cyanide is volatilised. The lead is then allowed to cool to near its point of solidification, and then run into an ingot-mould of polished steel.

I have also obtained lead by the reduction of the chloride. For this purpose I treated with an excess of dilute hydrochloric acid the carbonate of lead prepared by the action of sesquicarbonate of ammonia upon the sulphate of lead. The minute traces of iron contained in the carbonate remain dissolved in the excess of hydrochloric acid. I made use of two different plans to reduce the chloride. One consisted in mixing it with two-thirds of its weight of pure carbonate of soda and projecting the intimate mixture into fused cyanide of potassium. The metallic lead produced was poured into another crucible with a fresh quantity of pure fused cyanide of potassium. It is there kept at a high temperature and continually agitated until the surface, flat and dull as it is at first, becomes strongly convex and

brilliant. When sufficiently cool it is poured into an ingot-mould and kept away from moist air.

The other plan of reducing the chloride consists in heating an intimate mixture of it with carbonate of soda and black flux. The resulting lead was fused and agitated for some time in contact with air, and then heated with cyanide to remove the last traces of oxide.

Synthesis of Nitrate of Lead.—I effected the synthesis of nitrate of lead in absolutely the same manner as indicated in the case of nitrate of silver, taking all the precautions necessary to arrest the last traces of lead carried off by the gas during the solution of the metal, and sometimes during the evaporation of the solution of lead in nitric acid.

In general, to effect the solution of the metal, I employed the most concentrated acid which was capable of attacking it. Lead decomposes concentrated nitric acid, but very slowly, but, on the other hand, this only dissolves traces of the nitrate. This salt as it is formed precipitates in the form of a crystalline powder. The precipitation of the nitrate of lead during its formation is necessary for the success of the synthesis. This salt, in fact, not supporting an elevated temperature without decomposition, ought to be dried at a comparatively low temperature. The probability of a complete desiccation of this salt is only acquired with difficulty if it is deposited in even not very voluminous crystals, as is the case during the evaporation of a solution of the nitrate. The attack of 150 or 200 grammes of lead by a proper quantity of acid more or less concentrated, and under the influence of a continuous heat of 70° to 80°, requires from thirty-six to forty-eight hours. I have, moreover, found out that when once the action has commenced the heat must be kept up night and day, until the complete desiccation of the resulting salt. If this precaution is neglected the operation may be considered lost; for in this case when the saline mass is dried it slowly and continuously loses weight for six weeks, as I have found. In all the syntheses which are detailed in the Table I have taken the precaution to keep up the heat night and day after the action has once commenced until it no longer disengages a trace of acid under the influence of a temperature of 125° to 130°. By keeping the globe continually at a temperature notably below the boiling-point of the liquid which it contains, it requires from four to six days to bring to dryness the product of the attack of 150 to 250 grammes of lead. When brought to apparent dryness, 160 to 200 grammes require a continuous temperature of 140° to 155°, to be kept up during eight to twelve days in a current of dry and pure air to be brought to a constant weight. In this state of desiccation the temperature can be raised to nearly 200° in a current of air without experiencing further loss; but a little above that temperature acid vapours are evolved in a continuous manner.

I wished to know to what degree I could rely upon the desiccation of nitrate of lead in the state of a crystalline powder, and I found that 180.557 grammes of this salt precipitated by nitric acid from an aqueous solution, and consequently in the form of a crystalline powder, dried first at 125°, and then heated for three days at a temperature comprised between 125° and 140° lost 33.3 in weight. The same salt raised for eight days to 155° experienced a farther loss of 100.000ths of its weight. I kept it during thirty-six hours at 155° without causing it to undergo the slightest alteration in weight. From 195° to 200° it again commenced to disengage acid vapours, and did not cease until it was in part reduced to the state of basic nitrate. The limits

between the point at which nitrate of lead loses its last trace of acid and water and that at which it decomposes are therefore very narrow. From what I have above stated, this limit does not exceed 55°. The difficulty which is found in drying the nitrate without decomposing it explains why the results of the analyses of this salt by Berzelius, Anderson, and L. Svanberg agree so imperfectly. I have myself performed a great number which have equally given me the most contradictory figures; but this is of no present importance.

I have made two series of syntheses. In the first series all the nitrate was dried in a current of air. Having conceived some doubts of the possibility of thoroughly drying this salt without decomposing it, I undertook, a year and a-half later, a second series of experiments, but effecting this time the desiccation *in vacuo*. With this object, after having first heated to 80° for eleven days and nights the product of the solution of lead in nitric acid, to bring it to the state of dryness, and after having kept the salt at from 140° to 155° for a hundred and twenty hours, I applied a caoutchouc connector to the flask containing the salt and exhausted the air from it. The salt remained *in vacuo* from eight o'clock in the morning till eleven o'clock in the evening, the temperature being kept all the time at about 155°. During this time I allowed air to enter, and pumped it out again five times. I remarked that the air pumped out of the flask reddened litmus paper contained in a tube which the air had to pass through before arriving at the cylinders of the pump.

These are the details of one experiment. They show what confidence may be placed in the syntheses of nitrate of lead dried in the air:—

	Grammes.
Weight of the flask	493.862
Weight of the lead in air	100.007
Weight of the globe with the nitrate dried at 155° until the weight of the salt was constant	653.8215
Weight of the flask after the salt had been heated to 155° <i>in vacuo</i> for three hours	653.815
Weight of the flask the next day	653.616 ¹
Weight of the flask, the salt having been again heated to 155° <i>in vacuo</i> for three hours	653.812
Weight of the flask, the salt having been heated a third time for two hours	653.810
Weight of the flask the next day	653.8105

Thus, the greatest difference between the weight of the salt dried in air and *in vacuo* is 0.0115 grammes for 159.970 grammes of nitrate.

I repeat, that whatever may be the care which I have taken to obtain the complete desiccation of nitrate of lead, however remarkable is the concordance between the different syntheses, I conceive, however, that there may remain a legitimate doubt as to the possibility of absolutely drying such large quantities of salts when they cannot be raised to a high temperature without decomposition. Further experiment will decide this. All that I dare predict is, that chemists who place themselves under the same conditions as myself will find absolutely the same results.

It remains to be seen whether these conditions are favourable to a research of this kind, and even if the nitrate of lead is not too unstable to be used for a rigorous determination. The lead employed in the syntheses was prepared—

¹ Thus in the original, probably a misprint for 653.816

For Nos. I. and II. with the pure carbonate and cyanide of potassium.

For Nos. III. and IV. with black flux and carbonate of lead.

For Nos. V. and VI. with chloride of lead, carbonate of soda, and cyanide of potassium.

For Nos. VII. and VIII. with black flux and carbonate of lead.

For Nos. IX. and X. with chloride of lead, carbonate of soda, and black flux.

(To be continued.)

On the Oxalate of Iron,¹ by H. CROFT, D.C.L., Professor of Chemistry in University College, Toronto.

In No. 43 of the CHEMICAL NEWS, amongst extracts from foreign journals (*Comptes-Rendus*, 51—17), there appeared a short note on the so-called Quadroxalate of Iron, by Dr. Phipson, the formula being given as $\text{FeO} \cdot 4 \text{C}_2\text{O}_3$. The correct name representing its composition being given, it does not appear that there can be any typographical error in the formula, which would otherwise seem likely from the excessive improbability of the existence of an anhydrous quadroxalate of a heavy metallic oxide. The absurdity of the formula becomes still more apparent if the method of preparation be considered, viz. by precipitating ferrous sulphate by oxalic acid, or better by oxalate of ammonia. In this latter case, these two neutral salts must so decompose each other as to produce a highly acid insoluble compound and set free three equivalents of ammonia, by which the supernatant liquid must become strongly alkaline—a species of decomposition the writer believes to be as yet unknown in chemistry.

It is scarcely necessary to say that nothing of the kind takes place. The salt is described as being yellow, and giving with ferricyanide of potassium a green substance, owing to partial decomposition—a fact which is not altogether incomprehensible when it is remembered

that CfdyK_3 gives a blue colour with salts of FeO , and that blue and yellow produce green.

It is a pity that Dr. Phipson, when writing on the subject, should not have previously made himself acquainted with facts which have been known for nearly five-and-twenty years, the salt being nothing more than the ordinary oxalate of iron, containing two equivalents of water $\text{FeO} \cdot \text{C}_2\text{O}_3 + 2 \text{aq}$. This compound has been described by Vogel and Berzelius, its composition shown by Döbereiner and Rammelsberg, who appear to have proved that it differs from the rare mineral Humboldtite in containing half an equivalent more water, $\text{FeO} \cdot \text{C}_2\text{O}_3 + 1\frac{1}{2} \text{aq}$, and $\text{FeO} \cdot \text{C}_2\text{O}_3 + 2 \text{aq}$, or

corresponding to the manganous oxalate. More recently it has been examined by Souchay and Lensen in their extended investigation of the oxalates.

In order to test the matter still further, the salt was prepared by my pupils, Mr. Ramsay and Mr. Thompson, in both ways indicated by Dr. Phipson, using a large excess of oxalic acid in the one case and precipitating both from concentrated and from very dilute solutions. In both cases the precipitation takes place almost immediately.

The subjoined quantities of FeO were obtained. It will be observed that the amount of FeO is a little below the requisite quantity both in these analyses and in those of Rammelsberg which are appended, owing to the salt retaining a certain amount of hygroscopic water, unless dried for a long time at 100° ; and also to the fact, that when heated it is not perfectly oxidised unless the heat be continued for a long time or the residue be moistened with nitric acid and again heated, as was done in No. I. No. IV. was only air dried.

RAMMELSBURG.					
FeO	38'78	39'10	38'92	38'84	39'48

Additional Note by the Author.

The 17th number of the *Comptes-Rendus* having come to hand, the writer is enabled to give the analyses on which the above formula is founded, viz:—

FeO	19'35	19'44
C_2O_3	80'65	80'56
	100'00	100'00

From the exact accordance of the analyses, it is evident that the oxalic acid was not determined, but only calculated from the loss, and as the quantity of FeO is exactly one half of that obtained by other chemists, it seems probable that Dr. Phipson has made the ludicrous mistake of calculating the protoxide corresponding to the obtained peroxide as FeO , and not as Fe_2O_3 , and considered all the remainder as oxalic acid.

On the Chemico-Microscopical Characteristics of Butter and Lard, by JOHN HORSLEY, F.C.S.

HITHERTO I have had considerable difficulty in applying the microscope to the distinction of these substances, but according to the following method the thing is easy

¹ Canadian Journal of Science, XXXI, 18.

enough:—Take a piece of each pure butter and lard and dissolve them in a little benzole contained in separate vessels, and allow the benzole two or three days to evaporate as much as possible to near dryness. Then take a small shallow glass dish, place in the centre of it a little of the butter, cover this with a drop or two of strong ammonia, shake the dish for a minute or two to distribute the contents equally, and place it under the microscope. By using a half-inch power, the object glass will be seen to be studded with long black tufts of acicular crystals, such as I alluded to in my former paper, the ammonia appearing to have little or no action on them. The other portion of the butter will be in large transparent masses, which by reflected light are opaque.

Lard, on the other, presents no such appearance, there being only a few small crystalline tufts observable, which disappear after a time, and the whole becomes more or less transparent flakes of an irregular and indented character.

Being called away to the Gloucester Assizes on a professional case, I have not had time to examine other fats; but no doubt, by a similar proceeding, I shall get at their characteristics under the microscope, which I shall have pleasure in communicating if worthy of notice.

The Laboratory, Police Station, Cheltenham.

On Formic Acid and the Hemihedralism of Formiate of Strontia, by M. JACOBSEN.

FORMIC ACID, prepared from starch and neutralised with carbonate of strontia, produces, as is known, fine crystals of formiate of strontia with two equivalents of water, which are hemihedral, some being right-handed and others left-handed. M. Pasteur, who noticed this fact, equally remarked that the aqueous solution of this formiate has no action upon polarised light, which he explains by the presence of the two hemihedral forms.

When prepared from oxalic acid and from glycerin, formic acid gives rise to a formiate of strontia similar to the preceding, at least in appearance, but which nevertheless differs sufficiently from it to prevent the admission of the absolute identity of the two acids, and consequently the two salts. The former formiate gives in preference left-handed hemihedral crystals, while the crystals produced by the formiate from glycerin is especially distinguished by right-handed hemihedral facets, the left-handed facets being in this instance in quite a subordinate proportion, while in the formiate from starch the left-handed facets preponderate.—*Annal. de Physik und Chem.*, vol. cxiii., p. 493.

On Certain Properties of the Platinum Metals, particularly Ruthenium, by Dr. CLAUS.

(Continued from page 258, vol. III.)

On the other hand, is not rutheniate of potash still more closely connected with ferric salts by its decomposing so readily, and by its similar decomposition also into O_3 and Ru_2O_3 ? Iron and manganese have also like degrees of oxidation, MO and M_2O_3 , similar to the platinum metals, and the combination MO_2 , which is wanting in iron, is met with again in manganese. The green solution of manganate of potash has also certain analogies with the blue solutions of a less positive pair,—namely, that of rhodic and iridic acids. But the most striking analogy is that existing between ferrocyanide of potassium and

double cyanides with a composition similar to the osmic pair. If the ferrocyanide of potassium, instead of being yellow, were colourless, like the cyanides of these other metals, they might be considered identical, so similar are their reactions. Between the two last terms the iridium and rhodium pair occupy the middle, being connected on one hand with platinum pair and on the other with the osmium pair. I have not been able to discover the relations which may exist between these metals and copper, which is always found in platinum mines, in spite of the isomorphism of the copper with the ferrous and manganous oxides. It is possible that copper ought to be placed between the two terms of the middle of the second series. The property possessed by osmium and ruthenium of forming, with oxygen volatile combinations constituted in an identical manner, removes these metals from the platinum series and from all analogy with iron and manganese and connects them with the metalloids; while, on the contrary, their faculty for forming bases disconnects them from the metalloids. The following Table may help to elucidate the foregoing:—

Horizontal Series.

Positive end of the Horizontal Series.	Principal Series	Osmium	Iridium	Platinum	Vertical Series	Negative end of the Horizontal Series.
	Secondary Series	Ruthenium	Rhodium	Palladium		

Our knowledge of platinum metals has been considerably advanced by the new modes of analysis described by French chemists, particularly by the use of peroxide of barium for attacking osmide of iridium, by the new process of pulverising the ore, and by the large number of analyses of platinum ores already made. I have been particularly interested by the description of analyses of varieties of osmide of iridium,—analyses which lead to the conclusion that the quantity of ruthenium in these ores augments with the increase of osmium, and diminishes as the iridium augments,—a result incontestably proved by my own researches, and which is explained by the close connection existing between ruthenium and osmium. It has been equally well ascertained that osmide of iridium, in the form of clear, shining scales and tablets, is the ore containing the largest quantity of these two metals: while the dark gray, dendritic and dull ore often contains very little osmium or ruthenium, though, according to my researches, it is never entirely free from ruthenium. I was, consequently, greatly surprised that French chemists should in two cases have found a Russian ore containing no traces of it. The evident explanation of this fact is the difficulty there is in discovering ruthenium when it exists in the ore only in very small quantity. Fusion with saltpetre and potash would not in this case suffice to reveal the presence of ruthenium. In ores containing much osmium nothing is easier, because the osmium favours the attack on ruthenium. In this case, then, after fusion with saltpetre and potash, a solution of an intense orange colour is obtained, containing hardly any iridium. It is otherwise with ores containing little osmium and relatively, also, little ruthenium. According to the quantity of osmium present, these yield clear yellow, dark green, or even quite blue solutions, which contain much iridium dissolved to the state of iridiate of potash; so that in a blue solution the small quantity of ruthenium there present is entirely masked by the colour of the iridium. Moreover, all the ruthenium does not pass into the aqueous solution at the first fusion of the

powdered ore, but a notable portion of it remains with the undissolved iridiate of potass. This method becomes still more defective when the substance on which we act contains no osmium,—when, for instance, we commence, as our authors have done, by eliminating the osmium and then melting the residue of iridium, containing ruthenium, with potass and saltpetre. These circumstances, unknown to the French chemists, may explain why ruthenium has escaped their analyses.

When ruthenium cannot certainly be discovered by fusion with potass and saltpetre, and when it is necessary to separate it from the other metals, I make use of another method, which I have described elsewhere,—namely, by precipitating ruthenium from a solution of the metallic chlorides, by the addition of a small quantity of ammonia and by boiling. This method also has the disadvantage of succeeding only when there is a considerable quantity of ruthenium; nevertheless, there is at least the advantage of being able to separate the greater part of the other metals which impede the precipitation either by partial crystallisations or by consecutive treatments by water, after which a solution is obtained sufficiently rich in ruthenium to allow of its determination, not only qualitatively, but, in an approximate manner, quantitatively. To this end it is necessary to be acquainted with the following conditions on which this process is founded:—

1. Ruthenium is precipitated as sesquioxide by boiling from solutions rendered feebly alkaline by ammonia. This precipitate is a black, ruthenious sesquioxide. The same effect is produced with osmic chloride, which invariably gives the precipitate OsO_2 . Other metals, particularly iridium, give no precipitates under these circumstances. Red ruthenic chloride also yields in this way an ochre-yellow hydrate of ruthenioxide $\text{RuO}_2 \cdot 5\text{HO}$, but this precipitation is incomplete; it is much more certain in presence of ruthenious sesquichloride. Potash behaves like ammonia in this reaction, but its use is not advisable, on account of the facility with which it dissolves the oxide RuO_2 . No precipitate is produced if there is much iridium in the solution, but it is easy to determine the presence or absence of ruthenium. In fact, a solution of pure iridium, containing no ruthenium, is instantaneously decolorised by the addition of excess of caustic potass or ammonia. It remains for a long time thus perfectly transparent, and then, after several days, takes a beautiful blue colour. But if the iridium contains traces of ruthenium, the colour of the solution becomes fainter during the reaction, but does not disappear; it passes to a yellow-brown or reddish hue, and does not become decolorised for some time, at which point the solution becomes troubled and a slight brown or yellow precipitate is formed. If the iridium contains more ruthenium, yet not sufficient to produce a visible precipitate, its presence is betrayed by the intense red-purple colour assumed by the liquid, especially if potass is used. These are the most certain reactions for the qualitative determination of ruthenium.

2. Double salts of iridic chloride are not isomorphous with double salts of ruthenious sesquichloride; these salts then never crystallise together, but always separately. The latter are decidedly the most soluble. They are not so easily precipitated when a solution of ruthenious sesquioxide in hydrochloric acid is treated with this addition of ammoniacal salts in solution, as when salts of iridium in a solution of iridic chloride are used. Crystals of a salt of iridium are also much larger than those of a salt of ruthenium, to which circumstance the greater solubility of a salt of ruthenium is partly due. When

both salts are deposited as crystals, they are each insoluble in a dilute solution of sal-ammoniac, which affords a ready means of freeing them entirely from salts of rhodium and palladium chloride (not palladio chloride), which are freely soluble in the above solution.

3. The double salt of ruthenic chloride is isomorphous with the iridium salt, and can enter as a constituent part of an iridium combination. A small quantity of this salt is always produced simultaneously with the sesquichloride, when ruthenious sesquioxide is dissolved in aqua regia, and the larger the proportion of this menstruum, the more freely it is formed. This being the most soluble of all the double salts of the platinum metals, a large portion remains, even in presence of much iridium, in the mother-water, after the crystals of other salts are deposited.

Fractional Process of Precipitation and of Crystallization.—Osmide of iridium is melted in the ordinary way, with saltpetre and potash, and moistened with water; then carefully neutralised with sulphuric acid in order to precipitate the metallic acids in solution, always leaving the liquid with a slight alkaline reaction; then alcohol is added, and the whole boiled. Throw the mixture on a filter and carefully wash, in order to free it as far as possible from potash salts. The black metallic powder thus obtained still contains much potash, in the state of acid iridiates of potash, which is capable of converting the greater portion of the iridium into double iridic chloride, during the subsequent solution of the metallic powder. For this reason we evaporate to a considerable extent the aqua regia solution separated from the powder, until all the osmium is disengaged as osmic acid; then, if left to cool, the residue is deposited, most of the iridium is deposited in the state of double salt, and the liquid contains all the ruthenium, in a much greater degree of concentration, although always naturally associated with iridium.

We afterwards filter and add powdered sal-ammoniac, which causes the deposition of yet more iridium, as a black crystalline precipitate. The solution generally contains ruthenium so concentrated as to be separable from the iridium by precipitation. Now evaporate again and add more sal-ammoniac until the liquid begins to lose its colour, and most of the platinum metals are deposited as double salts; then leave it for several days, collect the residue on a filter, and wash it with water containing sal-ammoniac in solution, which completely eliminates iron and copper, and does not affect the ruthenium, and we get a residue of salts of iridium containing ruthenium, which, dissolved and boiled, with the addition of a little ammonia, yields a precipitate of ruthenious sesquioxide.

Fractional Method of Extraction.—This process is generally conducted in the same manner as the foregoing. The first quantities of double potassic salts, usually containing no ruthenium, are allowed to crystallise, and the liquid is separated from the crystals. Evaporate the liquid almost to dryness, adding the necessary quantity of sal-ammoniac, and wash the residue with a concentrated solution of sal-ammoniac, to free it from iron and copper. Treat the salt of iridium, containing ruthenium, first with a few drops of hydrochloric acid, so that the ruthenic combination undergoes no decomposition, then with a little water in a flat dish, and leave it for several days. Then filter, and we get a liquid containing most of the ruthenic salt, which, heated with ammonia, as indicated in a foregoing paragraph, yields a voluminous black precipitate, which

does not colour the liquid deeply. The salt of iridium, always charged with ruthenium, which remains on the filter, is again to be treated in a flat dish with a little water, and so on, repeating the same operation so long as ruthenium is dissolved, and until the salt of iridium is obtained pure. Collect all the ruthenium precipitates on the same filter. The aggregate is not then entirely pure, containing a small proportion of iridium; nevertheless, the surplus of iridium is compensated for by the loss always sustained in operating on solutions highly charged with iridium, in which a certain quantity always remains unprecipitated. The first solutions contain most ruthenium, yielding the largest and purest precipitates, without producing much coloration of the liquid. The later solutions, during precipitation, occasion the intense red colour characteristic of the mixture of salts of iridium and of ruthenium. After a time this reaction also disappears, but the solutions continue to yield the ruthenic reactions already described. It is better not to heat these solutions, but, adding a slight excess of ammonia, to leave them at rest at the ordinary temperature of the air, when they soon become turbid and produce a light brown or yellow precipitate, sparingly voluminous, consisting partly of a mixture of sesquioxide of ruthenium and ruthenic oxide, and partly of pure ruthenous oxide. In fact, the salt of iridium, an isomeric constituent with ruthenic chloride, is dissolved, and ammonia, without precipitating iridium, eliminates the yellow ruthenic oxide.

I employed this complicated method to obtain ruthenium from poor ores when unable to obtain rich ones. I have also made use of this mode of analysis in the absence of any better. Not till after the discovery of volatile hyper-ruthenic acid could I employ a simpler and more certain method,—a method based on the volatility of the above-mentioned combination, and on the supposition that the presence of iridium in no way hinders the formation of hyper-ruthenic acid. I was led to the use of this new method by an observation I made ten years ago, that a solution of ruthenium, treated by chlorate of potash and hydrochloric acid, loses all its ruthenium, under the form of a volatile product. Still, this method cannot be regarded as very simple, seeing that the newly-discovered volatile ruthenic combination necessitates certain precautions to avoid loss by volatilisation. There is no appreciable loss in melting ruthenium with caustic potash and saltpetre. A piece of paper soaked with alcohol does not blacken if held even for a long time over the heated mixture, and no smell of hyper-ruthenic acid is observable, though during the solution of the mixture a feeble odour of it is always given off. If ruthenious sesquioxide, which is obtained in treating this solution by alcohol, is dissolved in hydrochloric acid, the solution takes place without forming a volatile ruthenic combination; but there is some likelihood of loss if aqua regia is used as a solvent, for ruthenium is then placed under circumstances similar to those produced by the simultaneous action of chlorate of potash and hydrochloric acid. When it is necessary to estimate ruthenium precisely, the osmium must not be expelled previously by means of aqua regia, otherwise there would be some loss of ruthenium. Keeping these circumstances in mind, the following mode of analysis may be proposed, always admitting the supposition that other metals exercise no influence on the result. For the determination of ruthenium, a larger quantity of the metal than is generally used is required,—that is to say, at least ten grammes, which must all be reserved for the search for ruthenium, disregarding all the other consti-

tuents. Then melt the pulverised ore with potash and saltpetre, dissolve it in water, carefully neutralise it with an acid, and, adding some alcohol, heat it; then carefully wash the precipitate, which is a black metallic powder, in water, to eliminate the saltpetre and other potash salts. Dissolve this powder in hydrochloric acid, heat it in a retort with chlorate of potash and hydrochloric acid, and collect the volatile products in condensers containing alcohol. By this means ruthenium and osmium are obtained together, but their separation can be effected by alcohol, which instantly decomposes the ruthenic acid, though it takes some time to reduce the osmic acid; or, the two metals may be precipitated from their solution by sulphuretted hydrogen, and the sulphides thus obtained heated in a small, platinum vessel, in an oxygen current, which disengages sulphur and osmium as acids, while the ruthenium remains as ruthenic oxide. This is only a proposition, which I submit to other chemists, especially French chemists who have ruthenium at their disposal, and who take so much interest in the analysis of osmide of iridium. They will perhaps be induced to undertake these analyses when they read the present Memoir. My own attention being absorbed by other questions, these researches have for me but a secondary interest.

PHARMACY, TOXICOLOGY, &c.

Researches on Hypophosphite of Lime,
by M. GERARD JANSSEN.

1. Preparation.—The hypophosphites are seldom met with chemically pure. This is due to those terrible explosions to which the most skilful operator exposes himself in their preparation. Prompted by a well-grounded fear, he dare not conduct the process to the end, and the product obtained is more or less altered by foreign substances.

The properties attributed to such preparations cannot be those of the hypophosphites chemically pure. The author of these researches sought a new method of preparation, which would permit of obtaining these salts perfectly pure and without danger. He first investigated the causes of explosion. These he found to be due to, first, the action of heat and the oxygen of the air on the phosphuretted hydrogen (PH_3); second, the production of biposphuretted hydrogen (P_2H_4); third, the formation of a peculiar and very explosive compound, to which he gives the name of triphosphuretted bi-hydride (P_3H_2). This substance crystallises in hexagonal prisms. As long as the temperature of the mixture remains constant, there is no fear of explosion; but if, after the heat has decreased, it be then raised, the triphosphuretted bi-hydride is instantly decomposed into phosphorus and phosphuretted bi-hydride (PH_3), which takes fire spontaneously. Alcohol is the only compound which prevents these explosions, because it not only arrests the action of the oxygen of the air on the phosphuretted hydrogen and the production of biposphuretted hydrogen, but also, what is most important, the formation of phosphuretted bi-hydride.

To prepare the hypophosphite of lime, which may be taken as a type of these salts, a sufficient quantity of hydrate of lime is mixed with three times its weight of distilled water, to which a third of pure alcohol has been added. The mixture is introduced into a long-necked flask, heated gently in a sand-bath. When the mixture has attained a temperature of 50° to 60°C.

small pieces of phosphorus are gradually added until the action has entirely ceased. The apparatus is allowed to cool and the solution filtered through asbestos. The filtered liquid is freed from alcohol by distillation in a retort, the residual solution evaporated to perfect dryness, and the white powder thus obtained preserved in well-stoppered glass bottles.

The hypophosphite may be crystallised in the retort by a slow evaporation.

The action of the alcohol is thus explained:—The phosphorus, acting on the hydrate of lime by heat, gives hypophosphite of lime and phosphuretted hydrogen,

Two intermediate compounds are also formed,—biphosphuretted hydrogen, and triphosphuretted bi-hydride,

The alcohol decomposes these two compounds, forming phosphide of ethyl.¹ This again is decomposed by the base into hypophosphite and alcohol, a part, however, remaining mixed with the alcohol recovered by distillation. This may serve for a subsequent preparation.

The action terminates by a feeble evolution of hydrogen from the decomposition of the phosphuretted hydrogen, one part becoming combined during the operation with the oxygen of the air, forming water,

2. Properties.—Hypophosphite of lime is a white powder, inodorous, but of an acrid and burning taste. Deliquescent and very soluble in water; scarcely soluble in ether and absolute alcohol. Soluble in fixed and volatile oils, it is precipitated when they become rancid. It crystallises with difficulty; the crystals contain two equivalents of water ($PO, CaO, 2HO$). Its solution, exposed to the air, is transformed into carbonate and biphosphate of lime. It immediately decolorises a solution of sesquisulphate of manganese ($Mn_2O_3, 3SO_3$).

Sulphur, selenium, and tellurium also decompose it into phosphite, then into phosphate, with formation of sulphide, selenide, or telluride of calcium.

Boron, silicon, and carbon, decompose it by heat; borate, silicate, or carbonate of lime is formed, and phosphorus evolved in vapour.

Hydrogen decomposes it into phosphate and phosphuretted hydrogen.

Hydrochloric, hydriodic, hydrobromic, and hydrofluoric acids decompose it into phosphate, phosphuretted hydrogen, and a haloid salt.

Nitric acid converts it into phosphate, hyponitric acid being evolved.

The alkaline bases decompose it into phosphate and phosphide.

The alkaline carbonates when boiling, and the alkaline sulphates in the cold, transform it into an alkaline hypophosphite and carbonate or sulphate of lime.

It precipitates metallic gold from its solutions.

¹ The phosphide of ethyl thus obtained, when separated from the alcohol, is a limpid fluid, of a phosphuretted odour and burning taste. It is very volatile, burning at 9° C. It is soluble in alcohol; the solution has an opaline appearance. In water it separates in drops, like chloroform, which it also resembles in its anesthetic properties. It burns with an emerald-green flame, exhaling an intensely disagreeable odour. A little powdered tin, bismuth, or antimony, placed in the flame, causes the colour to pass to pale violet, and finally to pure white. The great danger which attends the preparation and manipulation of this substance has not yet permitted the author to study all its properties.

In a solution of nitrate of silver it produces a white precipitate, which rapidly turns brown; if the hypophosphite be added in excess in the cold it reduces the silver to the metallic state after some time; by the aid of heat the reduction is more rapid.

In a dilute solution of bichloride of mercury it produces a crystalline precipitate of chloride. If added in excess it reduces the mercury to the metallic state.

From a solution of sulphate of copper it precipitates the oxide, which a continued ebullition reduces to the metallic state.

3. Adulterations.—Hypophosphite of lime may contain phosphite, phosphate, or carbonate of lime. These three adulterations are separated by cold, distilled water, in which they are insoluble. The first gives off hyponitric acid when acted on by concentrated nitric acid; the second, calcined with a soluble salt of lead, gives globules which crystallise in regular polyhedrons; and the third gives off carbonic acid when treated with a strong acid.

It may also be adulterated with chloride of sodium, sulphate of lime, carbonate of magnesia, and oxide of zinc. These can be recognised by their usual tests.—*Répertoire de Chimie.*

On the Chemical Constituents of Coca Leaves,
by JNO. M. MAISCH.

THESE interesting leaves are beginning to attract considerable attention both in Europe and America; the accounts of learned travellers and of physicians, who have lived for a number of years in the districts where Erythroxylon coca is cultivated, and where the leaves are employed for the preservation of the bodily strength amid continued hardships, all these accounts agreeing in the main points, it was natural to expect that the reflecting physician would desire to investigate their adaptation for the cure of disease. The greatest drawback to such investigations is undoubtedly the limited supply of the leaves, but I believe a sufficient quantity might be found in the United States for experiments in our hospitals.

Several papers have within the last year found their way into the scientific journals; among these an analysis of the leaves performed by Dr. A. Niemann, in page 47, Vol. IV. of the CHEMICAL NEWS. The principal object of his investigations was to search for an alkaloid, which he separated in a pure state and analysed. The wax and tannin were separated incidentally in the process for liberating the alkaloid, so that we are still in the dark about its other constituents.

A few months ago, I obtained through the kindness of Professor Procter, a few ounces of coca leaves for the purpose of analysing them. I should have desired very much to pay attention likewise to those constituents which are probably of less importance in regard to their medical properties, but at all events I had to follow the course marked out by Dr. Niemann, so as not to lose the opportunity of obtaining a little of the new alkaloid, and study the other substances isolated by him.

Accordingly, 1500 grains of the coarsely-powdered leaves were exhausted in a funnel-displacer by alcohol mixed with a little sulphuric acid. The dark coloured brown-green tincture was agitated with an excess of milk of lime, which assumed a brownish-green colour; the filtrate therefrom, together with the washings with cold alcohol, was carefully neutralised with sulphuric acid, filtered from the greenish sulphate of lime and distilled. The aqueous residue separated but little resinous

matter, the filtrate therefrom was precipitated by carbonate of soda and the alkaloid gained in an impure state by shaking the mixture with ether and evaporating the light straw-coloured ethereal solution. The yield was four grains, and the alkaloid showed the behaviour described on page 43, Vol. IV. CHEMICAL NEWS.

On adding the milk of lime to the acid tincture, the peculiar tea-like odour of the leaves was strongly developed; but on the addition of the carbonate of soda another heavy and narcotic odour is observed; this is described by MacLagan and Niemann as reminding of nicotina. I observed this slight resemblance, but still the odour is very different.

I likewise found Dr. Niemann's statements correct regarding the vegetable wax and the tannin; though, owing to the small quantity operated on, I was unable to obtain the former in a snow-white condition. The second acid, which Niemann considers as tannin modified by nitric acid, I obtained also in solution contaminated with some of the latter acid.

The alkaloids of coffee and cacao, which, though in a less degree, possess properties similar to those of coca, contain more nitrogen than any other alkaloid known. The small per-centage of nitrogen ascertained in cocaina by Dr. Niemann, suggested the idea that it might probably be a product of decomposition, and that the odour developed by carbonate of soda, might perhaps be a nitrogenous body or another alkaloid. To ascertain this, and to find out whether one or two acids were contained in the tincture, the above process was repeated with the balance of leaves, weighing less than an ounce. The liquid, together with the precipitate occasioned by carbonate of soda, was introduced into a retort, the neck of which was connected with a bent glass tube, dipping into a little dilute muriatic acid. When heated over the spirit lamp, the concussions were so violent that it was deemed advisable to place the retort in a sand bath, so as to supply from the sides sufficient heat to distil the volatile substances, until a syrupy liquid remained behind, from which the alkaloid was separated by ether.

The muriatic acid, which was perfectly clear and colourless, now had an odour somewhat different from the original odour of the alkaline liquid, but it resembled that of the residue in the retort. The acid solution was rendered alkaline by carbonate of soda and agitated with ether, which took up the odorous principle leaving it behind on spontaneous evaporation as a soft resin-like coating. The odour of this mass is heavy, narcotic; the taste similar, somewhat acid; the behaviour to test paper, neutral, but exposed to the damp atmosphere of a rainy day, it had almost completely lost its odour and acquired an acid reaction and taste, and was now easily soluble in water and alcohol; the solubility of the odorous mass in these menstrua had not been tried. I omitted to mention that the hydrochloric acid solution was tested with the usual reagents for alkaloids: phosphomolybdic acid, and the chlorides of gold, mercury and platinum, without being disturbed by either.

This odorous principle, which I regard as a product of decomposition of some constituent, is therefore volatile with the vapours of water in a slight degree, but very changeable at least in a moist atmosphere. It is likely to be of great importance, as it is stated by several observers that an infusion of the leaves has different properties from the same leaves chewed with an alkali. Whether or not it is nitrogenous, must at present be left undecided.

The solution from which the alkaloid had been removed by ether, was digested with precipitated carbonate of

baryta, which removed all the sulphuric acid, and acquired a pale greyish-white colour. The filtrate was neutralised with acetic acid, and after the expulsion of the carbonic acid, rendered very slightly alkaline by a few drops of liquor ammoniac. An aqueous solution of neutral acetate of lead was now carefully dropped in, as long as a dirty greenish-brown precipitate was produced, which is voluminous, but settles in a few minutes and may be readily filtered and washed. On the further addition of neutral acetate of lead, a precipitate is separated which is at first yellowish-white, but settles readily to a greyish yellow.

The liquid filtered from this last precipitate is not disturbed on the further addition of sugar of lead, but yields with basic acetate of lead a nearly white voluminous precipitate, which is insoluble in water, but readily soluble in acids. Corrosive sublimate and deuto-nitrate of mercury do not disturb it; protonitrate of mercury yields a whitish precipitate, insoluble in water, almost entirely soluble in nitric acid; the white precipitate by nitrate of silver is scarcely taken up by nitric acid, but readily by ammonia. The liquid contains a small quantity of muriatic acid, but besides it an organic acid which imparts to it a brownish-yellow colour. This colour becomes deeper on exposure to the air, and after twenty-four hours' standing neutral acetate of lead produces a precipitate which resembles in colour the yellowish-white precipitate spoken of before. The filtrate was now of a pale yellow colour, and was not further disturbed by acetate or subacetate of lead after exposure to the air.

The first of the above-mentioned lead compounds dried to a dirty yellowish-brown powder; the second to a powder of a similar, but lighter colour.

The alkaloid which had been separated by ether from the alkaline solution left behind in the retort, was obtained as a transparent mass of the consistence of balsam tolu, a somewhat lighter colour, and of a heavy narcotic odour. All attempts to crystallise it failed, but it had still an alkaline reaction to test paper, was insoluble in water, but soluble in acids, which it completely neutralised. The solution in hydrochloric acid yielded with alkalis and their carbonates a white precipitate soluble in ammonia, with phosphomolybdic acid a voluminous yellowish-white, with bichloride of platinum a yellowish-grey, with terchloride of gold a bright yellow, with bichloride of mercury a voluminous white, afterwards flocculent, with iodine an orange-brown precipitate; no coloration was produced by this alkaloid with oxidising agents.

It will be seen from these experiments that this uncrystallisable alkaloid had very nearly the same behaviour as pure cocaina, the principal difference being the reaction with iodine, which, with the former, is of a somewhat lighter colour with a slight yellow tinge. Heat, it appears, therefore, renders it amorphous; what part the water and carbonate of soda take in this change must be determined by experiments with the pure alkaloid. But it is very likely that the yellowish-brown matter, which Dr. Niemann found so difficult to separate from cocaina, is this same alkaloid in an amorphous state.

My experiments likewise render it more than probable that the substance named cocatannic acid by Dr. Niemann, is a product of oxidation, the original compound of which yields with acetate of lead from a slightly ammoniacal solution no precipitate, but after previous oxidation by the atmosphere, precipitates it, and the precipitate has, according to the length of exposure, a colour varying from white to yellow and brown. As it

is so readily affected by the atmospheric oxygen, great care is necessary in its separation from the other constituents.—*American Journal of Pharmacy.*

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, December 5, 1861.

Dr. W. A. MILLER, F.R.S., in the Chair.

Dr. OPPENHEIM read a paper "*On the Camphor of Peppermint.*" This substance had been known for some time, but had lately been introduced in larger quantities than formerly. It was imported chiefly from Japan, packed in earthen vessels and presented an appearance resembling crystallized sulphate of magnesia, which in fact was sometimes employed to adulterate it. When washed with warm water and fused, it resembles common camphor; it melts at 36°C ., and boils at 210° ; these properties coinciding with those of the stearoptene examined by Dumas, obtained from American oil of peppermint. Its composition, as determined by analysis, agreed with the formula $\text{C}_{10}\text{H}_{16}\text{O}$. The corresponding hydro-carbon had also been prepared, its composition being $\text{C}_{10}\text{H}_{18}$. Some doubt still existed as to the constitution of this camphor, which appeared to border both on fatty and aromatic bodies; it differs from the camphor of Borneo by two equivalents of hydrogen, from ordinary camphor by four equivalents, and from capric acid by two of oxygen; it turns the plane of polarization to the left, and when crystallized from an alcoholic solution of soda, forms long needles. When exposed to the action of gaseous sulphurous or hydrochloric acid a compound is formed, but after some time the gas is given off and the camphor left; concentrated acids dissolve it freely, and it is reprecipitated by dilution or by neutralization with alkali, as an oily liquid which soon changes to the solid state. When heated to 170°C . with concentrated acetic acid the two combine to an oil which is not decomposed by water, and which distills at about 223° ; the same reaction takes place with the anhydrous acid, and the composition of the body formed is represented by the formula

one equivalent of hydrogen being substituted by acetyl. This substance turns the plane of polarization to the left more strongly than the camphor, an alcoholic solution of soda decomposes it with reproduction of the original camphor. Butyric acid also combines with this substance, and corresponding compounds with hydrochloric and hydriodic acid exist. When exposed to the action of sodium, hydrogen is evolved and a compound containing about one equivalent of sodium is obtained, which is decomposed by water but dissolves in alcohol and iodide of ethyle; on heating the latter solution crystals of an organic body containing iodine are deposited, and eventually iodide of sodium is formed. From these properties it was concluded that this camphor was a monatomic alcohol belonging to the series represented by the general formula $\text{C}_n\text{H}_{2n}\text{O}$: the name "menthol" was proposed for this body. By the action of anhydrous phosphoric acid or chloride of zinc, the corresponding hydro-carbon was obtained, and by exposing this to the action of bromine, a compound, $\text{C}_{10}\text{H}_{17}\text{Br}$, was formed, which was decomposed by potash with production of the hydro-carbon, $\text{C}_{10}\text{H}_{18}$. The corresponding acid had not as yet been formed, oxidising agents attacking the carbon of the camphor instead of the hydrogen.

Dr. ODLING thought that the experiments detailed did not prove this body to be an alcohol.

Dr. OPPENHEIM replied that, according to Berthollet's definition, an alcohol is an organic body which does not contain nitrogen, and which combines with acids giving up an equivalent quantity of hydrogen.

Mr. CHURCH remarked that the process for the formation of campholic acid by passing camphor vapour over soda-lime, contained in a tube and heated, yielded it in very small quantities, and that he should be glad to hear of a better process.

Dr. FRANKLAND having taken the chair,

Mr. J. C. FOSTER read a paper, "*On Piperic and Hydropiperic Acid.*" From the analyses that had been formerly made of piperic acid, three formulæ had been proposed, namely, $\text{C}_{22}\text{H}_{12}\text{O}_8$, $\text{C}_{30}\text{H}_{22}\text{O}_{10}$, and $\text{C}_{30}\text{H}_{22}\text{O}_{10}$, the last being preferred; the formula $\text{C}_{12}\text{H}_{10}\text{O}_4$ had also been given, the acid being considered monobasic. Mr. Foster's analyses confirmed the formula $\text{C}_{12}\text{H}_{10}\text{O}_4$ for the acid, and $\text{C}_{12}\text{H}_8\text{MO}_4$ for its salts. He had thought it possible that by the action of reducing agents a compound of the formula $\text{C}_{12}\text{H}_{10}\text{O}_2$ might be formed, and with this view the action of hydriodic acid was tried; this substance, however, charred the acid at a temperature below 100° . When submitted to the action of an amalgam of sodium, piperic acid yields a substance containing two additional equivalents of hydrogen, for which he proposed the name of hydropiperic acid, the composition being $\text{C}_{12}\text{H}_{12}\text{O}_4$. The hydropiperic acid melts at 64° and solidifies at about 56° , is not volatile without decomposition, is very slightly soluble in cold, more soluble in hot water, and on cooling the hot aqueous solution, it separates as an oil, which afterwards solidifies; it is soluble in alcohol and ether and may be obtained in large crystals from these solutions; with strong sulphuric or nitric acid it gives a red colour, and with dilute nitric acid a nitro product; when heated with excess of alkali, an acid of the formula $\text{C}_7\text{H}_6\text{O}_4$ was formed, which had already been prepared from piperic acid by the action of potash, and had been named proto-catechuric acid. Various salts of the hydropiperic acid were then described, among others an acid potash salt prepared by boiling carbonate of potash with an alcoholic solution of the acid; this salt was gradually decomposed by recrystallization, and completely by solution in water, the neutral salt being produced. The ether was prepared by passing hydrochloric acid gas into an alcoholic solution of the acid, a brown oil being formed, which, by the action of gaseous ammonia, furnished a substance which was probably hydropiperamide. With chloride of acetyl a neutral oil was obtained in which one equivalent of the hydrogen of the acid was replaced by acetyl.

Dr. FRANKLAND remarked that there was still a possibility of a reduction of piperic acid, although one or two reducing agents had failed; for since weak oxidizing agents were sometimes found to act more completely on certain bodies than powerful ones, the same might be found to be the case with reducing agents.

Dr. ODLING inquired whether hydropiperic acid was an appropriate name for a substance having such a relation with piperic acid.

A paper by Dr. DAUBENTY, "*On the Power Possessed by the Roots of Plants of Rejecting Poisons,*" was then read. The results of some former experiments in which the poisonous substances were applied to the plants after they had grown up, had already been communicated to the Society; in the present experiments these were introduced into the soil before the seed was sown; the substances tried being nitrates of baryta and of strontia, and arsenic acid instead of the arsenious acid used in the former experiments; barley and turnips were the crops employed, and the introduction of the poisonous bodies seemed rather favourable than otherwise as to the quantity of crop obtained. Neither of the substances tried were absorbed under these circumstances, and the only question that remained was whether the quantities employed were sufficient; a larger dose of arsenic, however, killed the plants,

but he proposed to try the effect of larger doses of the baryta and strontia salts.

Dr. FRANKLAND remarked that perhaps the plant absorbed very small quantities of these substances, and afterwards rejected them, so that the amount present in the plant at any one time was not sufficient to be detected.

The next paper was by Professor BOLLBY, "*On the Physical Properties of Alloys of Lead and Tin.*" The specific gravity of these alloys was subject to great variation, but an alloy containing equivalent quantities of lead and tin appeared to stand lowest in the series, an increase in the quantity of either metal causing an increase in the gravity. From this it was concluded that it was unsafe to infer what were the proportions of the metals in the alloy, from the specific gravity. With respect to the melting points there were great discrepancies in the determinations, but the solidifying point seemed to be more trustworthy; two solidifying points were observed to exist in every case, for an alloy of the composition Sn_2Pb remained liquid, the excess of metal, whether tin or lead, solidifying first. This alloy solidified at 181°C , which was lower than the melting point of either tin or lead.

The next paper was also by Professor BOLLBY, "*On the Dangers Arising from Feeding Steam Boilers with Certain Waters.*" It had hitherto been considered that waters containing only the carbonates of lime and magnesia were better for feeding boilers than those containing also sulphate of lime, because the sulphate made the deposit more stony, and the usual remedy recommended in the case of a water containing sulphates, was an alkaline carbonate, which decomposed the sulphate of lime; he had, however, found that some boilers which had been fed with water containing no sulphates, formed a stony incrustation to such an extent that the iron flue passing through the boiler became red hot. On inquiry it appeared that the refuse of some bleaching works was discharged into the river from which the supply was drawn. This refuse had a small quantity of fatty matter with it, which, although in very small quantity, completely prevented the deposit in the boiler being wetted by the water, and in fact, by digesting the deposit with ether, a perceptible quantity of fat was obtained. The same stony deposit was formed in another boiler in which the feed water was taken from the condenser of an engine, and in this case, also, a small quantity of grease was found to be the cause, and the addition of a little carbonate of soda to the water completely overcame the difficulty. The flues had only become red-hot when coal was substituted for wood, which had been previously employed as fuel, the coal giving a more intense local heat.

Mr. PERKIN remarked that he had found common clay, added in small quantities to the feed-water, prevented the adhesion of the deposit to the boiler.

Dr. FRANKLAND alluded to a similar case of a boiler forming a thick stony deposit, which had come under his own notice; in this case the feed-water was contaminated with organic matter, which caused it to have a sort of glutinosity; it might be poured from a great height without breaking into spray. The organic matter in this case was volatile, and was derived from the refuse of a starch factory, which was discharged into the river from which the supply was drawn.

NOTICES OF PATENTS.

663. *Manufacture of Gas from Coal, Oil, or Oleaginous Substances.* J. I. TAYLOR, Manchester. Dated March 16, 1861.

THE present invention relates to improvements upon an apparatus for manufacturing gas from the substances named

in the title, for which the patentee formerly obtained letters patent bearing date March 21, 1860. These improvements consist in the insertion of one or more diaphragms within the body of the retort, which otherwise retains the shape of that formerly used, the object of such addition being the increase of the heating surface, and, by a longer passage for the gas, more thoroughly effecting the conversion of the cily substances. With a view to economising the waste heat of the furnaces supplementary drying ovens and water-tanks are provided, the latter being connected directly with the retort and serving as a condenser for the liquid products of decomposition.

678. *Soap.* C. N. KOTTULA, Holborn, London. Dated March 18, 1861.

THIS invention refers to the introduction into soap of one or more of the following substances:—Bees'-wax, Japan wax, stearine, sperm, and similar materials. The patentee recommends also the combination of resin with soap, employed alone, or conjointly with one or more of the substances already named. These materials should be dissolved previously to their being mixed with the bulk of the soap.

The addition of yellow bees'-wax, or the white wax of Japan, would raise the cost of production without contributing in the same measure to improve the excellence of the soap. It is possible that from the high fusing points of these materials the compound soaps would be firmer, or could be made to hold a larger proportion of water. The addition of resin is an old expedient, and frequently practised in the manufacture of the lower qualities of soap.

717. *Soap.* F. G. WAGON, Issy, near Paris. Dated March 22, 1861. (Not proceeded with.)

THE inventor purposes to employ, as an earthy base in the manufacture of soap, carefully-washed kaolin, or China clay. This is recommended to be mixed by trituration with caustic potash, dissolved in water in the proportion of about one ounce of potash in the pint of water, and then added to the bulk of soap. For toilet use, the employment of glycerin and the ordinary perfumes is specially advised.

Of the mineral substances employed in the adulteration of soap, kaolin is that most frequently introduced. Its addition, like that of resin described in the preceding specification, is not calculated to improve the quality, but rather to increase the weight of the soap, serving only the same purpose as was pointed out by us¹ in reference to the manufacture of paper according to certain systems adopted in foreign countries.

684. *Preparation of Fish and Marine Animals for Manure.* J. JERRELL, Molde, Norway. Dated March 19, 1861. (Not proceeded with.)

By means of crushing rollers and suitable machinery it is proposed to break up the bony structure of the fish, and to subject the comminuted material to the action of a centrifugal drying apparatus and to an after desiccating treatment. By such a process it is stated to be possible to preserve the animal matters from decomposition until they are actually spread on the land to serve the purpose of manure.

697. *Preparing Caoutchouc for Dental Purposes, &c.* R. A. BROOMAN, Fleet Street, London. A Communication. Dated March 20, 1861. (Not proceeded with.)

THE inventor treats the ordinary red caoutchouc of commerce in the following manner to render it suitable for moulding dental pieces, (artificial gums,) and other objects to which the flesh-coloured material is applicable:—The red caoutchouc, coloured with vermilion or other pigment,

is first softened by sulphide of carbon, ether, chloroform, or other solvent employed in proportions varying from one quarter up to an equal weight with the caoutchouc; when so softened or dissolved an appropriate quantity of any of the white pigments specified is added for the purpose of altering the colour from red to pink, and to increase the brilliancy a little carmine may occasionally be added with advantage. Oxide of zinc is used alone or in conjunction with carbonate or sulphate of baryta, sulphate of strontia, or of manganese, phosphate of lime, calcined alumina or silica, or the latter in its precipitated condition. The decolourising agent is usually introduced in quantity about equal by weight to that of the red caoutchouc, and in some cases a small proportion of ordinary caoutchouc solution is required for the purpose of giving the paste more elastic qualities. After moulding, the dental piece or other object must be solidified by exposure in a closed vessel to temperatures ranging between 300 and 335 degrees Fahrenheit, from half to three-quarters of an hour being generally sufficient to communicate the requisite degree of hardness. The flesh colour will be improved by exposing the piece to the influence of the sun's rays, either directly or when immersed in a bath of alcohol.

Grants of Provisional Protection for Six Months.

2356. George Roberts, Bessborough Place, Pimlico, Middlesex, and Frederick Lambe, Cushion Court, Old Broad Street, London, "Certain improvements in lamps and lamp wicks, whereby they are adapted for more effectively burning animal, linseed, and other heavy and also glutinous and bituminous oils, and other burning fluids employed for illuminating purposes."—Petition recorded September 20, 1861.

CORRESPONDENCE.

Chemical Nomenclature.

To the Editor of the CHEMICAL NEWS.

SIR,—As it appears to be the fashion to find fault with our unfortunate chemical nomenclature and to propose new systems, perhaps I may be allowed to make a few remarks on the subject. I have read with interest Mr. Newlands' ingenious proposal for the simplification of chemical nomenclature, but, unless I am somewhat mistaken, it resembles very much the methods proposed by Dumas, Gmelin, and

Laurent, not only in its principles, but also in its results. These celebrated chemists were induced to abandon, or at any rate to modify to a very considerable extent, their methods of nomenclature, on account of the very complicated names at which they arrived; and I am almost afraid that Mr. Newlands has scarcely overcome this inconvenience, as his name for acetic acid (dagdatic acid) is not very much simpler than Laurent's term, "linavinam" for alcohol, and, in Laurent's words, I fear that, "in spite of their shortness, they have no chance of being adopted." Again, as the number of elements contained in the body increases, so the name becomes more complicated; thus, for ordinary alum we have the oft-quoted appellation, atolan-telmin-ojafin-weso. This name, although expressing most completely the composition of alum, even to the water of crystallisation, I think would not be adopted by many chemists. It would be well, certainly, to assign names expressing the composition to every new body that is discovered; but it would be somewhat difficult to change the names of all existing bodies, although there would certainly be many advantages in making the name of a substance express its composition.

There is one thing that ought certainly not to be lost sight of in any new nomenclature that may be proposed, and that is, that the constitution and type of a body should be expressed by its name as far as possible. This, as far as I know, has only been done in the case of the derivatives of ammonia, which is really the only part of the present chemical nomenclature that is at all systematic. Here we find something like what a nomenclature ought to be. The derivatives of this type, when basic, are called amines, and when neutral, amides. A basic compound derived by the replacement of hydrogen in one equivalent of ammonia is called a monamine; one derived from two equivalents of ammonia is a diamine; and one from three equivalents, a triamine, &c. These, again, are divided into primary, secondary, and tertiary monamines, diamines, triamines, &c. If the nitrogen in ammonia and its derivatives be replaced by phosphorus, arsenic, or antimony, we then have the phosphines, arsines, and stibines, which are divided into classes in the same manner as the nitrogen compounds. The most complicated of all these bodies is expressed by a simple name, although probably a long one. Let us take, for example, the compound called succinylsulphophenylidibenzoyldiamide. This is certainly a long word, containing not less than fifteen syllables, but it immediately tells us, as well as a name can, what this body contains and some of its properties. Beginning at the end of the word, we find the substance is a diamide,—that is, a neutral derivative, produced by the replacement of hydrogen in two equivalents of ammonia, and the hydrogen is replaced by one equivalent of succinyl, two of sulphophenyl, and two of benzoyl. The formula is, therefore:—

The name does not give us the composition of the radicals. Some proposal that would give short, concise, and expressive terms to these radicals would be a great advantage.

As this portion of our nomenclature seems so simple, it would not be advisable to alter it, at least, not at present; and if a nomenclature that would not interfere with the designation of the derivatives of ammonia could be found, it would stand more chance of adoption. It scarcely becomes one like myself to suggest any such system, but perhaps I may be allowed to say a few words in explanation of a system which has struck me as being not altogether destitute of advantages, and which, although I cannot and do not expect that it will ever be adopted, may prove acceptable to some of your readers, who may be able to improve upon it.

Chemical compounds were arranged by Gerhardt under four types,—viz., hydrogen, HH; hydrochloric acid, HCl; water, H₂O; and ammonia, H₃N. However, hydrochloric acid is a derivative of hydrogen; therefore, all its derivatives are also derived from hydrogen. Consequently, the hydrochloric acid type may be left out of consideration as a separate type. Since Gerhardt's time, however, another type has been proposed,—viz., the marsh gas, H₄C, or the silicuretted hydrogen type, H₄Si.

The names of the ammonia derivatives we have already spoken of; so we have the remaining three types,—the hydrogen, HH; the water, H₂O; and the marsh gas, H₄C.

We have first to fix upon a general termination for the derivatives of the three great types; and in the first type, that of hydrogen, *ide* might be convenient, as this type embraces all the hydrides, chlorides, bromides, iodides, fluorides, &c.; and as the termination *ide* would remind us of these combinations, it might be thought applicable in this case, but, for reasons that will appear immediately, the French termination *ure* will be more appropriate. Thus, as ammonia is trihydramine (I never heard it called by this name), hydrogen will become dihydrure, and the designations of the derivatives of hydrogen follow as a matter of course.

The one equivalentic metals, potassium for example, will be called dipotassure; and the two equivalentic metals, as platinum, will be platincure. (These terms are never likely to be used, any more than the name potasside of potassium for KK.) In the following list are a few of the organic derivatives of hydrogen:—

Hydride of ethyl C₂H₅H ethylhydrure.
Dihydride of ethylene (C₂H₄)''H₂ ethylenedihydrodiure, or more simply, ethylenedihydure.

Ethyl C₂H₅ C₂H₅ diethylure.
Methylethyl CH₃, C₂H₅ methylethylure.

Some of these terms are nearly as simple as the ordinary ones, but I cannot say this for the diethylure. The acid hydrides are:—

Hydrochloric acid HCl hydrochlorure.
Water H₂O dihydro-oxydiure, or dihydroxure.
Ammonia H₃N trihydronitrotriure, or trihydroniture.

Marsh gas H₄C tetrahydrocarboretture, or tetrahydrocarbure.

The derivatives of hydrochloric acid are named without difficulty:—

Chloride of potassium KCl potassiochlorure.
Dichloride of platinum Pt''Cl₂ platino-dichlorodiure, or platino-dichlorure.

Trichloride of gold Au''Cl₃ aurotrichlorotriure, or aurotrichlorure.

Chloride of ethyl C₂H₅Cl ethylchlorure.
Dichloride of ethylene (C₂H₄)''Cl₂ ethylenedichlorodiure, or ethylenedichlorure.

Tribromide of glyceryl (C₃H₅)'''Br₃ glyceryltribromotriure, or glyceryltribromure.

Chloride of acetyl C₂H₃OCl acetylchlorure.
Dichloride of succinyl (C₄H₃O₂)''Cl₂ succinylchlorodiure, or succinylchlorure, &c.

The water type includes the oxides, sulphides, selenides, tellurides, oxy salts, sulphur salts, &c. The most convenient termination for this series is probably *ide*, as the terms oxide and sulphide are so familiar. If this termination were employed for the hydrogen derivatives, we should be compelled to look for a different termination for this type. The termination *ate* might be used, but I think it would scarcely be so appropriate.

Water $\begin{array}{c} H \\ H \end{array}$ } O dihydroxide.

Sulphuretted hydrogen $\begin{matrix} \text{H} \\ \text{H} \end{matrix}$ S dihydrosulphide.
As seldom to be used as oxide and sulphide of hydrogen.

Hydrate of potassium $\begin{matrix} \text{K} \\ \text{H} \end{matrix}$ O potassiohydroxide.

Sulphhydrate of potassium $\begin{matrix} \text{K} \\ \text{H} \end{matrix}$ S potassiohydrosulphide

Hydrogen being as much a radical as potassium, deserves to be represented in the name of the compounds of which it forms a part.

Oxide of potassium $\begin{matrix} \text{K} \\ \text{K} \end{matrix}$ O dipotassio-oxide.

Sulphide of potassium $\begin{matrix} \text{K} \\ \text{K} \end{matrix}$ S dipotassio-sulphide.

Hydrate of bismuth $\begin{matrix} \text{Bi}''' \\ \text{H}_2 \end{matrix}$ O₂ bismutho - trihydrotri-oxide.

Alcohol $\begin{matrix} \text{C}_2\text{H}_5 \\ \text{H} \end{matrix}$ O ethylhydroxide.

Ether $\begin{matrix} \text{C}_2\text{H}_5 \\ \text{C}_2\text{H}_5 \end{matrix}$ O diethyloxide.

Glycol $\begin{matrix} (\text{C}_2\text{H}_4)'' \\ \text{H}_2 \end{matrix}$ O₂ ethylenedihydrodi-oxide.

Oxide of ethylene $\begin{matrix} (\text{C}_2\text{H}_4)'' \\ \text{O} \end{matrix}$ ethyleneoxide.

Glycerine $\begin{matrix} (\text{C}_3\text{H}_5)''' \\ \text{H}_2 \end{matrix}$ O₂ glyceryltrihydrotri-oxide.

$\begin{matrix} (\text{C}_3\text{H}_5)''' \\ (\text{C}_3\text{H}_5)''' \end{matrix}$ O₂ glyceryltri-oxide.

Hypochlorous acid $\begin{matrix} \text{H} \\ \text{Cl} \end{matrix}$ O hydrochloroxide.

Chloric acid $\begin{matrix} \text{H} \\ \text{ClO}_2 \end{matrix}$ O hydrochloryloxi-oxide.

Sulphuric acid $\begin{matrix} \text{H}_2 \\ (\text{SO}_2)'' \end{matrix}$ O₂ dihydrosulphuryldi-oxide.

Phosphoric acid $\begin{matrix} \text{H}_2 \\ (\text{PO})'' \end{matrix}$ O₂ trihydrophosphoryl-oxide.

$\begin{matrix} \text{H} \\ \text{Cl} \end{matrix}$ O hydrochloroxide.

$\begin{matrix} \text{H} \\ \text{ClO}_2 \end{matrix}$ O hydrochloryloxi-oxide.

$\begin{matrix} \text{H}_2 \\ (\text{SO}_2)'' \end{matrix}$ O₂ dihydrosulphuryldi-oxide.

$\begin{matrix} \text{H}_2 \\ (\text{PO})'' \end{matrix}$ O₂ trihydrophosphoryl-oxide.

Hypochlorous acid $\begin{matrix} \text{H} \\ \text{Cl} \end{matrix}$ O hydrochloroxide.

Hydrate of potassium $\begin{matrix} \text{K} \\ \text{H} \end{matrix}$ O potassiohydroxide.

The nomenclature of the anhydrides is of course similar to that of the anhydrous oxides,

Hypochlorous an- $\begin{matrix} \text{Cl} \\ \text{Cl} \end{matrix}$ O dichloroxide.

hydride $\begin{matrix} \text{ClO}_2 \\ \text{ClO}_2 \end{matrix}$ O dichloryloxi-oxide.

Chloric anhydride $\begin{matrix} \text{ClO}_2 \\ \text{ClO}_2 \end{matrix}$ O dichloryloxi-oxide.

Sulphuric anhydride $\begin{matrix} (\text{SO}_2)'' \\ (\text{PO})'' \end{matrix}$ O sulphuryloxi-oxide.

Phosphoric anhy- $\begin{matrix} (\text{PO})'' \\ (\text{PO})'' \end{matrix}$ O₂ diphosphoryltri-oxide.

dride $\begin{matrix} (\text{PO})'' \\ (\text{PO})'' \end{matrix}$ O₂ diphosphoryltri-oxide.

Acetic acid $\begin{matrix} \text{H} \\ \text{C}_2\text{H}_3\text{O} \end{matrix}$ O hydroacetyl-oxide.

Acetic anhydride $\begin{matrix} \text{C}_2\text{H}_3\text{O} \\ \text{C}_2\text{H}_3\text{O} \end{matrix}$ O diacetyl-oxide.

Succinic acid $\begin{matrix} \text{H}_2 \\ (\text{C}_4\text{H}_4\text{O}_2)'' \end{matrix}$ O₂ dihydrosuccinyldi-oxide.

Succinic anhydride $\begin{matrix} (\text{C}_4\text{H}_4\text{O}_2)'' \\ (\text{C}_4\text{H}_4\text{O}_2)'' \end{matrix}$ O₂ succinyl-oxide.

Citric acid $\begin{matrix} \text{H}_2 \\ (\text{C}_6\text{H}_6\text{O}_3)''' \end{matrix}$ O₂ trihydrocitryltri-oxide.

Citric anhydride $\begin{matrix} (\text{C}_6\text{H}_6\text{O}_3)''' \\ (\text{C}_6\text{H}_6\text{O}_3)''' \end{matrix}$ O₂ dicitryltri-oxide.

The sulphur acids and salts of course follow the same rules,

Sulphocarbonic acid $\begin{matrix} \text{H}_2 \\ (\text{CS})'' \end{matrix}$ S₂ dihydrosulphocarbonyldisulphide.

Sulphocarbonic anhydride $(\text{CS})''$ S sulphocarbonylsulphide.

The nomenclature of the salts is obvious.

Acetate of silver $\begin{matrix} \text{Ag} \\ \text{C}_2\text{H}_3\text{O} \end{matrix}$ O argentoacetyl-oxide.

Primary sulphate of potassium $\begin{matrix} \text{K} \\ (\text{SO}_2)'' \end{matrix}$ O₂ potassiohydrosulphuryldioxide.

We have now only to mention the last type, H_2C . There are only few derivatives of this type, but names must be in readiness for these compounds when discovered. The termination *uret* may be applicable in this case.

Marsh gas H_2C tetrahydrocarburet.
Siliciuretted hydrogen H_4Si tetrahydrodisilicuret.

I know that there are very many weak points in the system that I have taken the liberty of describing, and that it will be very much ridiculed. One of the greatest difficulties is to find appropriate names for the different radicals. I have tried once or twice to concoct some terms, but they became so barbarous that I abandoned the attempt. However, we have the names of the radicals of the fatty alcohols, if we like to employ them,—I mean the nomenclature of these bodies used by Gerhardt,—viz.: trityl, tetryl, &c.; we might have monyl, or elayl, and deutyl, but they would not replace the names methyl and ethyl, for some time at least. There is, unfortunately, too little, and yet too much, distinction between the alcohol and acid radicals; too little in the fact that they all end in *yl*, and too much, as we do not see the relation between the radicals of the same series. We see no relation between ethyl and acetyl by the name; and if we adopt Professor Williamson's suggestion, and call acetyl ethyl, then we must have omethyl, opropyl, &c. Perhaps, if the termination *oyl* were employed for the name of the acid radical, it might have some benefit; however, in this case, the similarity might be too great: thus—methyl methoyl, ethyl ethoyl, bear a great resemblance to one another. There would be a confusion in the case of caproyl and eapryl, but that would not be new.

In conclusion, I have only to apologise for having written at such length; but if you should think these remarks worth admission to your Journal, they might be the means of directing others who are more competent for the task than I am to propose some systematic nomenclature which would be of lasting benefit to our science.—I am, &c. HERBERT McLEOD.

London, December 4.

To the Editor of the CHEMICAL NEWS.

SIR,—Will Mr. Newlands be kind enough to say what will be the name for albumen according to his proposed new system of nomenclature?—I am, &c.

INQUIRER.

Bath for High Temperatures.

To the Editor of the CHEMICAL NEWS.

SIR,—Some time ago, having occasion to use a bath capable of affording a temperature considerably above that of boiling water, my friend Mr. Tichborne suggested to me the use of glycerine instead of the ordinary saline baths. I tried a mixture of glycerine and water and found it to answer so well the purpose for which it was intended, that I thought it would be worth while to make known a few particulars which might prove useful to chemists.

I found the boiling-point of a mixture of six parts water with one part glycerine (by measure) to be about 218° F.; with equal parts glycerine and water, 230°; and by using six parts glycerine with two of water, the temperature was raised to, and remained steady at 250°. If the proportion of glycerine be much increased beyond

this point, acrid fumes are given off on heating the mixture.

The glycerine which I used in these experiments, though otherwise pure, had frequently been accidentally exposed to the air, and had doubtless, absorbed some moisture from the atmosphere; therefore, the results given above may be looked upon as correct for the mixtures experimented upon, though perhaps they may not hold good when other samples of glycerine are used.

I am, &c. EMERSON REYNOLDS.

Estimating the Value of Aniline.

To the Editor of the CHEMICAL NEWS.

SIR,—Can any of your Correspondents inform me of any quick and sure method of estimating the value of aniline, and the amount of any one of its homologues present in a mixture of them? Precipitation of the platinum salt and calcination does not give all that is required; and to form a certain quantity of colour and test the amount produced is only approximative, and by rectifying at boiling points many errors may creep in.—I am, &c.

BENZOL.

On the Adulteration of Butter.

To the Editor of the CHEMICAL NEWS.

SIR,—Before proceeding to the detail of another test for the presence of fats in butter, I feel that the note of Mr. Horsley in the last Number of the CHEMICAL NEWS calls for a brief remark. So far from wishing to "condemn" the utility of the ether test, I think that we are all indebted to Mr. Horsley for publishing it; and I am willing to acknowledge and announce that he has been the first to make public any test at all by which this adulteration is to be discovered. I agree with him that ether does detect lard when mixed with butter in small proportions very readily and satisfactorily, but not exactly when used in the manner he details. I think, as he describes its use, the appearance of the deposit may have misled him, and induced him to think that lard is the common adulterant. It may so happen, too, that the "fresh" butter I have examined in London may really be adulterated with a different substance to the butter which he has analysed in Cheltenham.

Again, I think Mr. Horsley has misunderstood me when he says that the ether test can readily identify other kinds of fat than lard, while those I have put forward will not detect any but beef dripping. I don't think I stated this. On the contrary, the peculiarities of both mutton fat or dripping—for I have used the terms "fat" and "dripping" synonymously—and of lard come out as remarkably as those of beef fat on melting with boiling water in a beaker, &c., as I propose showing in my next paper. I do not desire to disparage the use of ether, but still it appears to me that a service is rendered if it is shown that what everybody has at hand suffices to detect these substances in butter. I am sure Mr. Horsley is equally desirous with myself to arrive at the truth; and with this view, as I shall always be pleased with any criticism that he may bestow upon my observations, I hope, in all friendliness, he will not object to my criticising his.

I am, &c. EDWARD BALLARD, M.D.

Parochial Laboratory, Islington, December 9.

MISCELLANEOUS.

Sulphur in California.—The refining of sulphur has been commenced as a business in Santa Barbara county, Cal. Twenty miles south-eastward of the town of Santa Barbara, and seven miles back from the Mission of San Buenaventura, which is upon the sea shore, is a great bed of native sulphur, deposited in remote ages by the vapors and waters of sulphur springs. The country in the vicinity bears strong marks of volcanic action. The sulphur deposits back of San Buenaventura have long

been known, but only lately has it been rendered valuable. Messrs. Davidson, Spence & Co. commenced about the first of this year to open the mine. The *Daily Alta* says, that there were then some half a dozen men at work in the mine, and this sulphur is so abundant and accessible, that the time is perhaps not far distant when it will be shipped to Europe. The crude deposit is stated to comprise 80 per cent. of sulphur.—*Scientific American*.

Chemical Society.—The next meeting of this Society will take place on Thursday evening next at Burlington House, at eight p.m., when the following papers will be read:—Dr. Bence Jones, "On the Simultaneous Variations of Hippuric and Uric Acids in Healthy Human Urine;" Mr. G. F. Rodwell, "On the Solubility of Sulphate of Lead in Hydrochloric and Nitric Acids."

Taking Notes of Lectures.—There is one cause especially which I believe has tended to depreciate the value of lectures as a means of instruction. It is the common practice which students fall into, of taking very copious notes whilst in attendance upon them. This is a great mistake, for if a student during a lecture have his eye constantly directed upon the paper on which he is simply recording the words of the lecturer, instead of directing his principal attention to the lecturer himself and the illustrations which he is employing, he necessarily loses in a great measure the effect which must be otherwise produced by the words as they flow from the earnest and high-minded teacher; and at the same time he will gain but an imperfect acquaintance with the details and mode in which experiments have been performed, or of the nature of the specimens exhibited for the elucidation and demonstration of the subject-matter of the discourse; and hence the advantages he would otherwise derive from attendance upon lectures over those of simple reading, are, in a great measure, lost. My advice to a student, therefore, is, to take notes only of the "heads" of the lecture, or at least, not to allow note-taking to interfere with his attention to the lecturer, and afterwards whilst the lecturer with his apparatus and specimens are photographed as it were in his memory, to fill in the details by reading and thinking over what he has heard.—*Professor Bentley*.

ANSWERS TO CORRESPONDENTS.

C. G.—It has not yet been mentioned in our pages. We will bear it in mind.

Treatment of Tar.—W. writes, Where can I get good information as to the treatment of tar, and refuse from gas works, the method of making naphtha, paraffin, and dyes from tar, &c.?

Ignoramus.—In inhaling air containing carbonic acid, a large quantity is taken into the lungs, where it comes in contact with the blood. But in drinking aerated beverages, a small quantity only is taken into the stomach. The action of an agent in one instance has nothing to do with its effect in the other case.

Browning for Gun Barrels.—Armourer.—Take tincture of perchloride of iron $\frac{1}{2}$ oz., spirit of nitric ether $\frac{1}{2}$ oz., sulphate of copper 2 scruples, distilled or rain water $\frac{1}{2}$ pint. Clean the barrel with lime and water, and apply with a sponge. When dry, polish with a stiff brush or iron scratch brush.

G. C. C.—1. Sulphite of soda is made by passing sulphurous acid into caustic soda; sulphide of sodium, by passing sulphuretted hydrogen into the same alkali. Which do you mean? 2. Your question would require a long explanation in answer; read some elementary work on Physics and Meteorology.

Filtering-Paper.—Our opinion has been asked respecting a kind of filtering-paper, supplied by Wilcox and Co., advertised as "chemically pure, and the cheapest ever made." It is of a whity brown colour and upon burning leaves a reddish brown ash. Four sheets $7\frac{1}{2}$ inches in diameter were found to yield, upon combustion, 0.694 grains of ash. This is much less than that yielded by ordinary white filtering paper, at even a higher price, although it is nearly double that left by the best Swedish paper. The paper, when in use, is very strong, and filters quickly, without, at the same time, allowing any of the precipitate to pass through. Taking into consideration the low price at which it is offered, it will be found a very valuable article for general qualitative work, although it is not to be recommended for delicate or quantitative experiments.

Books Received.—"Elementary Treatise on Physics." By Professor A. Ganot. English Edition. Part III. London: H. Baillière. "A Set of Chemical Tables," on six large sheets, arranged by Dr. Galloway. London: John Churchill.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Chemical Researches on the Assay of Silver by the Moist Way, by G. J. MULDER, *Math. Mag. Phil. Nat. Medicinæ, Artis Obstetriciæ et Pharmaceuticæ Doctor, Professor of Chemistry at the University of Utrecht, Grand Cross of the Order of the Netherlands Lion; of the Luxembourg Order of the Couronne de Chêne; of the Swedish Orders of Wasa and Polar Star, &c., &c.*

(Continued from page 298.)

It is well known that the temperature exerts in most cases a very great influence on the solubility of substances in liquids; the solubility is hereby often increased. What, now, is the influence of the temperature of the liquid submitted to the assay on the quantity of chloride of silver which remains soluble in the nitrate of soda? The answer to this question is of great importance, as much for the assay experiments as for scientific interest.

I took a solution of one gramme of pure silver, which was first treated at 18° C. with 100 cubic centimètres of salt standard solution, and was further brought to the limit of precipitation with decimal solution of salt, and then treated again with decimal silver solution, and again with decimal solution of salt, the temperature remaining at 18° C. The bottle which contained the liquid was now heated to about 30°, and at that temperature the decimal solution of silver was added unto the limits of precipitability. The temperature was then raised to from 45° to 55°, and at this it was kept or brought to it again previous—that, after strong shaking, a fresh addition of silver or salt solution was added. Finally, it was cooled down to 25°.

The results of these experiments are sufficiently significant to be quoted in full. The drops have been added two by two every time until a perceptible precipitate ceased to make its appearance:—

	Decimal solutions.	
At temperature of 18° C.	22 drops of solution of silver	
" " 18° C.	22 " " salt	
" " 30° C. about	35 " " silver	
From 45° to 55° C.	60 " " salt	
" 45° to 55° C.	60 " " silver	
" 45° to 55° C.	60 " " salt	
At temperature of 25° C. about	47 " " silver	
" " 25° C. about	29 " " salt	

The precipitation has been effected with the greatest care, and has never been carried over the limits; but the influence of the rise and fall of the temperature has occasioned a certain anomaly which was quite unavoidable. When we take the sum of the drops of silver and salt, we have:—

¹ It deserves to be noticed that at this temperature the precipitate as soon as formed gets immediately dissolved, as long, at least, as 40 drops have not been fully added; and it requires a very experienced eye to distinguish the precipitate properly.

Silver.	Salt.
164 drops, or 8.2 a.c.	171 drops, or 8.6 a.c.

This agrees so closely that we may declare the result a good one. The experiment remained the same at the end as in the beginning, and if it had been carried again up to 18° C. the required quantity of 22 drops would have made its appearance again; but the risk of discolouration of the chloride of silver prevented the longer continuation of the experiment. The main point is this, that at a temperature of from 45° to 55° the quantity of chloride of silver dissolved in 0.787 grammes of nitrate of soda and 100 cubic centimètres of water is almost three times as large as at 18° C. We have already learned that the silver which remains this way in solution when the assay is made with 1 gramme of pure silver and 100 cubic centimètres of standard solution, weighs 1 milligramme, the temperature being at from 15° to 17°. Without anything else being changed, the increase of temperature (45°—55° C.) increases the weight of silver dissolved three times—i.e., 3 milligrammes remain in solution. A decrease of temperature has just the opposite effect, as the following experiment will show:—

One gramme of pure silver was first dissolved in 5 cubic centimètres of nitric acid, then precipitated at a temperature of from 15° to 17° C. with 100 cubic centimètres of standard salt solution, and afterwards cooled to 5° C., and treated first with decimal solution of salt and *vice versa* with silver and salt (decimal solutions), the mutual precipitate was produced, the temperature being kept at 5° C. The results were the following:—

Silver.	Salt.
A 13 drops	B 13 drops
C 13 drops	D 13 drops

At a temperature of 5° C. 13 drops only of the solutions of silver and salt were required to produce the mutual precipitate unto the ultimate limit: 13 drops = 0.65 milligrammes of silver, or its equivalent proportion of salt. We have, therefore, the following series: 0.787 grammes of nitrate of soda and 100 cubic centimètres of water dissolve—

	Chloride of silver or silver.	
	Weight in milligrammes.	
	Cl. Ag.	Ag.
At 5° C.	0.86	0.65
At 15°—17° C.	1.33	1.0
At 45°—55° C.	3.99	3.0

Two other points deserve our attention: viz., the influence of and excess of free nitric acid, and the influence of nitrate of copper on the origin of the mutual precipitate. The former—i.e., excess of free nitric acid—occurs in the ordinary assay of pure silver, while the former again with the latter are met with in the assays of alloys of silver and copper. The quantity of nitric acid and its strength, degree of concentration, are not very strictly taken when an assay is made, while the quantity of copper in the alloys is subject to much variation, and the quantity of nitrate of copper must consequently vary also; and if these two agents, nitric acid and

nitrate of copper, have any influence, then it is necessary to ascertain the quantity and quality of that influence. The following experiments were made:—

a. 1 gramme of pure silver was dissolved in 5 cubic centimetres of nitric acid.

b. 1 gramme of pure silver was dissolved in 10 cubic centimetres of nitric acid.

c. 1 gramme of pure silver and 1 gramme of pure copper were dissolved in 7.5 cubic centimetres of nitric acid.

These solutions were precipitated with 100 cubic centimetres of standard salt solution, and were afterwards treated with decimal solution of salt, so as to bring them to the utmost limit; temperature—16.5° C.

We have further determined the quantity of silver required in order to reduce the precipitate produced by decimal solution of silver to the ultimate limit. The following quantities of decimal solution of silver were required at 16.5° C.:—

For a	20 drops
For b	22 drops
For c	20 drops

This result agrees so closely with that we have obtained for pure silver (see page 204 Vol. IV. No. 98) that we have every right to conclude that, provided the temperature of the vessels in which the assay liquids under experiment are kept remain constant, much nitric acid or much copper exert no influence upon the origin of the mutual precipitate. It is true the experiment was not carried on so as to precipitate again with decimal solution of salt and again with decimal solution of silver; but this was not necessary, for what has been once well observed remains constantly the same under the same circumstances. We have already learned that chloride of silver is more or less soluble in nitric acid, indifferently, whether it be more or less concentrated. Chloride of silver is also soluble in nitrate of silver, but it is so sparingly so that it is of no influence on the silver assays. From what has been treated here we may draw the following conclusions:—

That there are sources of errors in the method of assay by the wet way, even if pure silver be used, which errors depend, first, on the quantity of nitrate of soda; secondly, on the quantity of water; and, thirdly, on the temperature.

It is necessary, and I found it to have a great practical influence, to inquire more accurately into some of these particulars. The quantity of water, it is true, may differ about from two to three cubic centimetres. That difference has not been proved to me to exert any very decided influence upon the assays and experiments connected therewith; but the quantity of nitrate of soda may differ, if care be not taken to employ, when experimenting upon alloys, not from 1000 milligrammes of the alloy, but from 1000 milligrammes of pure silver present in the alloy, in order to secure always the presence of 0.787 gramme of nitrate of soda in the liquid. For instance, let the alloy to be tested be at $\frac{11.1}{1000}$ ths, it is then necessary to weigh according to this equation, $775 : 1000 = 1000 : x$, which gives $x = 1.2903$ in that quantity 1000 of silver occurs, and 1000 of silver will always yield exactly the constant quantity of nitrate of soda.

It will be said, that this is done merely because the pipette usually employed is filled with 100 cubic centimetres of the standard solution. I say it must be done,

* This expression *utmost limit* is a short expression for the one we so frequently require to use—viz., *utmost or ultimate limit of precipitability*.

not because the same pipette is used, but because every other quantity of nitrate of soda in the liquid gives rise to different results, if, at least, the experiment be carried so far as to precipitate with salt unto the limit of precipitability. It fortunately so happens that not many substances do exert such a disturbing influence as nitrate of soda exerts in these experiments. The following experiments may elucidate this point:—I made an assay experiment to which I will have to refer afterwards again, in which, with one gramme of pure silver, 0.5 gramme of sulphate of protoxide of manganese, 0.4 gramme of cadmium, 0.1 gramme of iron, and 0.5 gramme of zinc—the three latter in a metallic state, were dissolved in nitric acid at the end of the experiment—I applied decimal silver solution unto the limit, the temperature being 16° C. I repeated the experiment with 1 gramme of pure silver and 0.6 gramme of sulphate of nickel, also with 1 gramme of pure silver and 0.1 gramme of oxalate of cobalt. The nitrates of these metals had no perceptible influence on the quantity of silver required, after the decimal solution of salt had been used to precipitate to the limit. To come again to the limit of precipitability these quantities were the following:—

Pure silver	20 drops
Ditto	20 "
Manganese, iron, cadmium, zinc	20 "
Nickel	20 "
Cobalt	20 "

No trace even of influence of the presence of the nitrates of all these metals can be observed to act upon the solubility of the chloride of silver; and though we do not mean to deny that they (*i. e.*, these nitrates) may exert some influence, it is beyond the limits of our experimental observation and of no consequence to the assays.

It is different with the nitrates of the alkalies and alkaline earths, which we will treat of afterwards, when we discuss the equivalent weights of silver and common salt.

(To be continued.)

On the Adulteration of Butter with Animal Fats,
by EDWARD BALLARD, M.D. Lond., M.R.C.P.,
Medical Officer of Health for Islington, and Parochial
Analyst under the Adulteration of Food Act.

[SECOND COMMUNICATION.]

In the short paper which I took the liberty to send a few weeks ago for insertion in the CHEMICAL NEWS, I ventured to enumerate certain physical indications of the existence of fatty adulterations in butter. I do not pretend to assert that all of them are of equal value. The colour, for example, of true butter will vary with season, with the nature of the feed of the cows, and probably, also, with their state of health. And the pressure-test also may vary with a variety of circumstances; but of those I mentioned, there are three which are, I believe, always to be relied upon. These are, the size of the drops which rise when the butter is melted and well stirred circularly with boiling water, and the consequent fineness or coarseness of the resulting appearances of cellulation; the granulation or sago-like appearance of the butter when the cold cake is removed in the adulterated butter, the globules sometimes being as large or larger than the largest grains of sago; and, lastly, the taste of the dried butter. The latter, I believe, is especially to be relied upon. It must be a very small adulteration indeed that will not now be detected by the palate; and these indications I have recapitulated are

not confined to [adulterations with beef fat or dripping, as I have been misunderstood to assert. The same phenomena are observed when mutton-fat or lard are the adulterants; and in these cases not only is there a similar appearance in the melted layer and in the granulations, but the taste detects severally mutton fat, from its more tallowy flavour, especially if it have been melted down for some time, and lard from the very distinctive impression it makes upon the palate. I do not think any mistake can occur. I mentioned as an instance the adulteration with an equal weight of beef dripping; but a fourth part of fat, beef, mutton, or lard, gives similar indications, and very markedly too,—quite unmistakably.

As to the question whether lard or beef or mutton fat is the most common adulterant. There are parties in London whose sole business it is to deal with the butchers and others in fat. Among these I have had inquiries instituted. It appears that the destination of it is as follows:—The persons to whom it is sold first of all very carefully pick out every bit of pork fat, however small, and it is purchased by pastrycooks and chemists, both of whom find it to their advantage to prepare their own lard. The beef and mutton fat go to the melters, who select the suitable and best bits, which they boil down and pack in casks for parties at Ostend and other places, for the undisguised purpose of mixing with butter. There is no secret in this among persons engaged in the trade. The rest is prepared for the soap-boilers and others. I am further informed that for the preparation of butter beef fat is preferred. A few years ago there was, however, such a scarcity of fat, at Ostend that mutton fat, &c., were taken indiscriminately.

And now for the ether test, as put forward by Mr. Horsley. Since the publication of his letter I have made some experiments respecting it, the result of which I may as well detail before proceeding further. Mr. Horsley's statements are, that, first, pure butter ought entirely to dissolve when covered with ether at 65°; second, that the purest lard is more or less insoluble under similar circumstances, and that the same may be said of dripping, mutton suet, tallow, &c.; and, third, he distinguishes these several substances by the appearance of the precipitates, stating that that from lard is very fine and smooth, whilst that from dripping is granular and crystalline, and that from tallow long and thread-like, laying piled up one above the other. In my own experiments I used an apparatus which enabled me to weigh the precipitate, as well as to observe its character during the solution; and I used a constant quantity of the butter or fat to be tested, and a definite quantity of ether. In this way I hoped to attain more precise results. The difficulty I had to contend against was that of collecting and weighing the deposit without risking the loss of ether by evaporation, and the deposition of some of the dissolved-out matters by lowered temperature during the operation. The expedient I hit upon was this:—I take an ordinary test-tube, about 4½ inches long and about one inch wide, and fit it as accurately as possible with a good cork. I then take a piece of thin glass tube about ⅔ths or ½ an inch diameter, and from 1½ to 2 inches long—pieces of broken test-tubes do very well—and turn over the edges, so as to form a lip at each end. Over one end I tie with thread, tightly stretched, a little bit of thin linen rag, and round the tube beneath the other lip another piece of thread, leaving one end long. This, with a water-bath, constitutes my apparatus. In each experiment I used 20 grains of butter or fat to be tested, which I weigh in the cylinder,

and then let the latter down into the test-tube by the thread. I pour in the ether, directing it into the cylinder, and the thread hanging out of the tube. I put in the cork firmly and tie over with a leather cap. The tube is then immersed in the water-bath, at 65°, and at the expiration of an hour—this being the time I have mostly allowed for solution—the cap is removed, the cylinder drawn up by the thread without the necessity of removing the cork, the cap put on again, and the cylinder left for the ether to drain off from the deposit, the temperature of the bath still being maintained. As soon as the ether appears to have drained away, I remove the cylinder from the tube, and, closing the open end with my finger, press the other end upon a pad of blotting-paper, so as to free the linen and deposit by its imbibition from all remaining ether and soluble matter. When no further stain is imparted to the blotting-paper, I hang the cylinder in the air to dry; and when all smell of ether has passed off, weigh the cylinder and deposit, deducting the weight of the former.

In order to be sure about the matter, I obtained some butter churned specially for me by a friend in Bedfordshire, and with this, which arrived fresh and unsalted, I proceeded to experiment, and I adulterated it as follows:—1, I prepared an adulteration with equal weights of this and strained beef dripping; 2, one with three parts of butter and one of the dripping; 3, one with three parts of butter and one of strained mutton dripping; 4, one of equal parts of butter and pure, home-made, unsalted lard; 5, one of three parts of butter and one part of the lard. I also subjected to experiment separately the lard and beef dripping. My results were as follows:—

The butter and all the mixtures were washed with boiling water, and the cold cake thoroughly dried.

1. Results of exposure of 20 grains for one hour in the cylinder with one fluid drachm of ether.

- | | |
|---|--|
| a. Pure butter | Residue 2·4 grains—Residue firm, coherent, smooth, forming a little cupped mass of form represented in the margin; not absolutely white, not smelling of tallow or lard. |
| b. Beef dripping | Residue 12·6 grains—A rough looking mass, smelling strongly of tallow. |
| c. Lard | Residue 12·0 grains—Smooth, very white, smelling of lard. |
| d. Butter containing an equal weight of beef dripping | Residue 9·0 grains—A rough looking mass, smelling of tallow. |
| e. Butter containing one-fourth of beef dripping | Residue 4·0 grains—Resembling in shape and appearance that from butter, but whiter, and smelling somewhat of tallow. |
| f. Butter containing one-fourth of mutton dripping | Residue 4·0 grains—Resembling the preceding. |
| g. Butter containing one-fourth of lard | Residue 2·0 grains—Residue in shape, when dried, flatter than that from butter or that adulterated with one-fourth of dripping; less smooth on surface, less coherent, and fissured as in margin, whiter also, more brittle, and not smelling of tallow. |

I prepared another sample of this adulteration, and in place of allowing the cake to cool undisturbed, stirred it from time to time, so as to incorporate a little water with it, which is then not separable entirely either by blotting paper or by the desiccator. This powerful physical retention of water in interspaces of the fat is a distinguishing character of lard, and it is imparted to a marked extent to the butter adulterated with it. A specimen thus prepared and dried, as far as it could be, we will mark γ .

- γ . Butter with one-fourth lard } Residue 1.8 grains—Forming a flat cake upon the linen covering it universally, and fissuring or drying in all directions. Through this deposit the ether drained off very slowly.

2. Results of exposure of 20 grains for one hour in the cylinder with two fluid drachms of ether.

- a. Pure butter } Residue 1.8 grains—Of same appearance and character as in experiment with 3j., but the mass is thinner. Before separation the residue was suspended in the ether in the form of a coherent flocculence, entangling a few air bubbles. The ether drained away rapidly.

- b. Butter containing one-fourth part of beef dripping } Residue 1.1 grains—Residue much like that of pure butter. The precipitate before separation was powdery-looking, not so fine as that from lard. Ether drained away quickly.

- c. Butter containing one-fourth of lard } Residue 1.1 grains—Residue resembling that from 3j. of ether, but whiter. Before draining it formed a close flocculence in the ether. Ether drained away quickly.

- γ . Butter with one-fourth lard } Residue 0.9 grains—Residue very white, but resembling that from 3j. ether. Before draining it formed a dense, very firm, smooth deposit on linen, and the ether drained away extremely slowly.

A sample of δ , prepared in a similar manner to γ , also formed a dense deposit on the linen, but the ether drained away more quickly, and the deposit when dry was of the ordinary character, and weighed 1 grain.

The conclusions, I think, which may fairly be drawn are as follows:—

1. A certain portion of butter is insoluble at 65° in ether, used in the moderate quantities which are fitted for the proposed analysis. Perhaps other samples of butter would give even a larger per-centage of residue.

2. The appearance of the deposit as it lies in the ether (3j.) assists the diagnosis.

3. So also does the slowness with which the ether drains away from that formed from butter adulterated with lard and prepared as γ .

4. The form and appearance of the dried residue as it lies in the cylinder distinguishes butter adulterated with lard on the one hand from pure butter or butter adulterated with beef or mutton fat on the other.

5. The tallowy odour of the residue from butter adulterated with beef or mutton fat distinguishes it from that afforded by pure butter or lard.

6. Not quite half the weight of beef dripping and lard is taken up in the course of an hour by 3j. of ether at 65° . A longer exposure of lard (for several hours) caused all but six grains to be taken up. In each instance much less is taken up than is taken up from butter.

7. The presence of an excess of butter increases the solubility of the fat or lard mixed with it. The residue from the adulteration with one-fourth of dripping (beef or mutton) was greater than that from butter whether 3j. or 3ij. of ether were used; but the residue was less than it should have been (by calculation) for the quantity of fat present. In the case of lard, the solubility was so much increased by the butter, that the residue, with 3j. of ether, was absolutely less than that from pure butter, and the colour was so much whiter that one must believe that the presence of the lard promoted the solution of the butter also.

8. When the butter was not in excess, the residue from that adulterated with beef dripping was remarkably large, exceeding that which might be inferred from calculation. I obtained nine grains from the adulteration with an equal proportion of beef fat in two consecutive analyses.

9. So far as the comparative quantity of residue is concerned, nothing is gained from the use of more than one fluid drachm of ether to twenty grains of the butter to be tested. In fact, where 3ij. were used, the residue from the butter adulterated with a fourth of lard or of dripping was actually less than that from pure butter.

Researches on the Relations existing between Atomic Weights, by M. J. S. STAS, Member of the Royal Academy of Belgium.

(Continued from page 309.)

Synthesis of Sulphate of Lead.—In nearly all determinations of lead, chemists bring the metal to the state of sulphate, in order to weigh it. After having performed so large a number of delicate analyses, I do not hesitate to declare that there does not exist any which present so many difficulties and uncertainties, even when surrounded with the most minute and fastidious precautions. Berzelius has already remarked the extreme difficulty which is experienced in bringing to a satisfactory conclusion a synthesis of sulphate of lead.

I first attempted to perform these determinations in a refractory glass, but in this manner I obtained the most contradictory results. When it is attempted to heat the sulphate of lead the glass is attacked even before the excess of sulphuric acid is entirely driven off. It is, therefore, indispensable to perform the operation in platinum vessels. These are the arrangements which I eventually adopted:—

So as to save the labour—more considerable than would be supposed—of preparing the quantities of lead necessary to determinations of this kind, I combined some of the syntheses of nitrate of lead with those of the sulphate of this metal. Thus, the nitrate obtained in the synthesis No. IV. was transformed into sulphate. No. I. in the following Table shows the result. The nitrates produced in the experiments Nos. V., VII., VIII., IX., and X. were likewise converted into sulphates, the results being successively shown in Nos. II., III., IV., V., and VI. I effected this transformation in the fol-

lowing manner:—The nitrate of lead derived from a known weight of lead was dissolved in the smallest possible quantity of pure water, and the solution was poured into the weighed cucurbit of a platinum retort, containing an amount of pure dilute sulphuric acid, a little more than sufficient to transform all the lead into sulphate. After a convenient repose the acid liquid, which had become quite clear, was removed with a pipette and introduced into a very large platinum dish, which had been weighed, together with the platinum retort, and immediately submitted to evaporation over a water-bath, protecting as much as possible the surface from contamination from suspended matters in the air. The glass globe which contained the nitrate was repeatedly washed in pure water. All the washing-waters were added to the cucurbit already containing the sulphate of lead.

A small quantity of sulphuric acid was then poured into the liquid in the cucurbit to be certain that there was no more lead in the state of nitrate. In proportion as the liquid in the dish evaporated I replaced it by a fresh quantity taken from the cucurbit. In order to remove as much as possible the excess of sulphuric acid and all fixed soluble matter, I washed the sulphate two separate times in pure water. All the washing-waters, perfectly cleared by standing, were added to the liquid in the dish and evaporated in their turn. Then I exposed the cucurbit to a steam heat to dry the sulphate of lead. When, under the influence of a temperature of 100°, it disengaged no more vapour whatever, I embedded it deeply in a bath of magnesia, and raised it gradually to dull redness. After the volatilisation of traces of sulphuric acid, I saw appear in all my experiments nitrous vapours. As these vapours might be derived from the presence of some traces of nitrate of lead carried down by the sulphate in each experiment and after the vessel was cool, I moistened the salt with water very slightly acidulated with pure sulphuric acid. I again dried the mass over the water-bath, and calcined the sulphate a second time by heating the vessel in a magnesia bath. I never, in this second calcination, saw red vapours appear.

In all my experiments the sulphate of lead was of a dazzling whiteness. Its desiccation was effected with such care that the side of the cucurbit did not show any trace of projection.

To preserve the sulphate of lead during its cooling from atmospheric moisture, I suspended in the interior of the cucurbit a vessel containing chloride of calcium. This vessel was attached to a glass rod passing through the neck of the moveable head. The opening of the neck was besides closed with a cork.

I now return to the washing waters of the sulphate of lead. The platinum dish which contained them was kept on the water bath as long as its contents disengaged vapours. After all the liquid capable of volatilising at 100° was dissipated, I covered the platinum dish with a porcelain capsule larger than it, and having a hole bored in its upper part. Through the hole in the capsule I passed a glass tube nearly down to the surface of the liquid residue contained in the platinum dish. I then disengaged pure ammonia to transform the sulphuric and nitric acid which the dish contained into sulphate and nitrate. When the mass was almost solidified, I placed the dish in a bath of magnesia and heated it very gently to redness. Towards 300° the sulphate of ammonia decomposes into volatile products, and the capsule contains absolutely nothing but the sulphate of lead mixed with the traces of foreign matters existing

in the lead or the sulphuric acid. To eliminate the soluble sulphates which the sulphate of lead in the capsule could contain, I always wash the salt in water very slightly acidulated with sulphuric acid. After the washing and drying, I calcined a second time the small quantity of sulphate thus obtained.

In the first two determinations which I made, I had the misfortune to throw away the washing waters. I am therefore ignorant whether they contained any fixed product. In the four following I evaporated them down in a weighed platinum dish. The residue which I heated to redness weighed:—

In No. III. . .	0.0140	grammes, consisting of alkaline sulphates with traces of iron and copper.
In No. IV. . .	0.0193	do.
In No. V. . .	0.0190	do.
In No. VI. . .	0.0205	do.

These alkaline sulphates were evidently derived from the potassium and the sodium contained in the lead employed. I ought to add that the little sulphate of lead obtained from the evaporation of the washing waters was not absolutely white, even after having been a second time calcined with a mixture of sulphuric and nitric acid. It had a grey tinge.

After cooling for five hours free from moist air, the retort and the platinum dish were both weighed together in the large balance.

Before giving the result of these laborious experiments, I ought to point out a cause of error which I overlooked. I weighed the sulphate of lead in air; but this salt can condense so large a quantity of air as to be sensible with the enormous masses experimented upon. There is a means of ascertaining this fact and correcting the result subsequently if there is really an error of this kind, which would not surprise me.

I have abstained from correcting the weight of the sulphate of lead produced from 100 parts of lead by the weight of the foreign metals obtained in the state of sulphate in the residue of the washing waters of the lead salt, because I consider this correction as being more or less arbitrary, ignorant as I am of the proportion between the potassium and the sodium in these alkaline sulphates. Moreover, the presence in the lead of these excessively minute traces of foreign metals diminishes the weight of the sulphate of lead. The result would therefore be higher if the metal employed had been absolutely pure, and that would remove me still further from the figure, calculated according to Prout's law.

(To be continued.)

On Alum in Bread and Flour, by JOHN HORSLEY, F.C.S. Lond., Analyst to the County of Gloucester.

THE question of alum in bread having often proved a knotty point, and many errors having been made by mistaking other earthy precipitates for alumina, because a white precipitate was obtained on the addition of ammonia to the water in which bread had been soaked, as well as a similar precipitate by the use of either nitrate of baryta, or chloride of barium, the latter being supposed to have reference to the sulphuric acid of the alum salt, when, in fact, it may be due to the sulphate of lime existing in the water which was incorporated with the flour in making the loaf, or to the hard water in which the bread was soaked, I have drawn up the following paper, which contains *in extenso* the precise mode of manipulation which I am accustomed to follow, and which is of a thoroughly practical and reliable character.

The detection of alum in bread or flour consists of three points—viz., the existence of sulphuric acid, potassa, and alumina. If the two former are found, the latter may also be inferred.

Neither sulphuric acid nor alumina are to be found in incinerated wheat corn or flour, and a minute quantity only of potash obtains in it, and that in the form of a phosphate. An abnormal quantity, therefore, of that alkali, conjoined with sulphuric acid, being found in the water on making a preliminary trial by steeping a portion of the suspected bread in it, forms a satisfactory guide to further operations.

In order to get at these ingredients, we must first burn a thousand or more grains of bread or flour to a cinder in an iron dish or earthenware crucible, powder it finely, and burn it afresh till it be reduced to a small bulk—an operation of several hours; boil this in distilled water for a short time, and decant on to a filter, boil the residue again and again with fresh portions of distilled water till it ceases to produce any reaction on turmeric paper, indicating the entire extraction of the phosphate and sulphate of potash, the amount of liquid required being about 12 or 14 ounces.

By this treatment you will have extracted not only all the sulphuric acid and the potash—two of the aforesaid elements of baker's alum—but whatever common salt had been used. By concentration, if necessary, of this liquor, freely acidifying it with nitric acid, and then treating it with nitrate of baryta solution, the sulphuric may be precipitated and the sulphate of potash converted into nitrate of potash. The chlorine likewise may be separated from the common salt by nitrate of silver forming nitrate of soda and chloride of silver. The liquor filtered from the last precipitate should now be evaporated to dryness, and the joint weight of both nitrates taken. These being re-dissolved in water and treated with bichloride of platinum, the resulting dry precipitate determines the amount of potash as well as the soda remaining in solution.

The alumina, the only remaining ingredient left behind in the charcoal as an insoluble phosphate, can be extracted by digesting the charcoal first in cold nitro-hydrochloric acid diluted with a little water, and allowing it to stand a few hours; then boiling, filtering, and washing out all soluble matter with distilled water till ammonia ceases to produce any precipitate. Evaporate the filtrate and mixed washings to absolute dryness over a water bath, when we obtain as a residuum chloride of calcium and

chloride of magnesium, with peroxide of iron and phosphate of alumina, the latter, owing to the continued heat, having parted with its chlorine. The peculiar white pearly aspect of the dried mixture will at once indicate the presence of alumina, which, on the addition of distilled water, separates in flocculi. Project the whole on a filter, and wash the residue from time to time with water until it ceases to precipitate with oxalate of potassa, ammonia, or nitrate of silver. Reserving the residue on the filter, we proceed to precipitate, if required, the lime from the filtrate by oxalate of potassa in slight excess, followed by the addition of a little acetic acid, filtering, and evaporating the clear liquor to dryness, incinerating and digesting the residue in distilled water, when carbonate of magnesia and a little oxide of iron precipitate.

The precipitate of iron and phosphate of alumina previously obtained should now be treated with a boiling solution of pure caustic potash, which separates the alumina from the insoluble oxide of iron—sometimes a white precipitate of phosphate of iron may be obtained without any alumina existing—filter, freely acidulate with hydrochloric acid, add ammonia in excess, and boil, when the alumina will be thrown down, mixed with some phosphoric acid, to remove which it may be re-dissolved in hydrochloric acid, diluted with distilled water, carbonate of potash added in excess to precipitate the alumina, and then taking it up again by the careful addition of more hydrochloric acid till the liquid is clear. Now add a tolerable quantity of a solution of tannin, followed by q. s. of a solution of carbonate of potash, not to neutralise the tannic, but the hydrochloric acid, which, by the precipitation of the tannin with the alumina, becomes too free. This must be kept in check or the tannate of alumina cannot fall. By carefully operating in this way, first with tannin and hydrochloric acid and then with q. s. of solution of carbonate of potash, the whole of the alumina may be extracted, and on evaporating the residuary liquor to dryness and incinerating the salt obtained, it will be found to consist of phosphate of potash and chloride of potassium. The dried tannate of alumina should now be boiled with a little strong sulphuric acid, so as to char the organic matter; white fumes will be given off, and after a few minutes distilled water should be added, and the mixture boiled till all the alumina is dissolved. Add caustic potash in excess, then some free hydrochloric acid, and lastly, precipitate the alumina with carbonate of ammonia and boiling. Or instead of tannin, silicic acid may be used for precipitating the alumina, thus: Dissolve the phosphate of alumina in liquor potassæ, dilute with water, and add q. s. of soluble silicate of potassa. A gelatinous silicate of alumina forms, which must be projected on a cloth filter and well washed. Press the residue and collect in an evaporating dish; treat with hydrochloric acid, and evaporate to dryness over a steam bath. The residue being then digested in distilled water, the chloride of aluminum is dissolved out, and the insoluble silica precipitated. On this liquor being filtered, the addition of carbonate of ammonia will, with a slight boil, yield the pure alumina, the whole of the phosphoric acid remaining behind in the filtered liquor as phosphate of ammonia.

As liquor potassæ generally contains traces of alumina, previous experiments should be made on it so as to ascertain the probable amount, for which a deduction or allowance should be made in estimating the alumina extracted from the bread.

PHARMACY, TOXICOLOGY, &c.

New Process for the Extraction of Quinine and the Estimation of the Alkaloids of the Quinquinas, by M. RABOURDIN.

Extraction of Quinine.—I base this process on the property possessed by fixed caustic alkalies employed in excess to dissolve tannin, insoluble cinchona red, the colouring and resinous matters of quinquinas, without touching the quinine.

My method consists in reducing the bark to powder, and treating it in the cold in a displacement apparatus with water containing three per cent. of hydrochloric acid. I cease pouring in liquid when that which passes has but little taste.

Into the liquid which has passed through, and which amounts to eight or ten times the weight of the bark employed, I pour solution of caustic soda, in quantity about equal in weight to the original bark, and well agitate the whole. The quinine precipitates in white caseous flocks, which settle rapidly; the deep-red supernatant liquid is decanted, and the precipitate collected on a linen filter and washed with a small quantity of water.

Almost entirely composed of quinine, this precipitate may be purified by two methods:—

1. If it is acted on by a quantity of dilute hydrochloric acid insufficient to dissolve the whole of the alkaloid, there is obtained on filtration a colourless solution, which yields with ammonia white and pure quinine.

2. If the precipitate is to be entirely exhausted, a slight excess of acid must be used. In this case there is obtained upon filtration a slightly-coloured liquid, which is bleached in the following manner:—Pour into the hydrochloric solution dilute ammonia until a brown precipitate appears, and upon filtration a colourless liquid is obtained. If, in consequence of the addition of an excess of ammonia, white flocks appear mixed with the brown precipitate, acidulated water must be added until these are dissolved. Ammonia precipitates quinine from the clear and colourless filtrate. In this state it is perfectly white, and only contains traces of cinchonine.

This process appears to me to introduce great economy in the manufacture of salts of quinine,—first, by suppressing the employment of alcohol as a solvent; and second, by avoiding the precipitation of the quinine by lime, and, consequently, the drying of this calcareous precipitate by artificial heat; third, by suppressing the employment of animal black as a decolorising agent; and, fourth, I may affirm, by yielding a more abundant product; for, indeed, this method permits me to obtain so readily the whole quantity of alkaloid contained in quinquinas that I propose it as a means of estimating the value of barks in commerce. The three official quinquinas are equally well treated by this method. When I wish to estimate gray bark I take forty grammes, but only ten grammes in the case of the Calissaya and red barks.

Mode of Assay.—I take ten grammes of Calissaya quinquina in fine powder, and moisten it with water acidulated with four per cent. of hydrochloric acid. The powder is then arranged uniformly in a long tube, provided with a plug of cotton, and exhausted with the same acidulated water with which it was moistened. If the displacement takes place with regularity, and no local caking together of the powder takes place, it is exhausted when there are obtained between 100 and 120 grammes

of filtrate. Into this liquid there are then poured twelve to fifteen grammes of caustic soda solution, which is well mixed by agitation. The precipitate is then collected on a filter and washed with a little water as long as any red liquid passes through.

When the filter has well drained it is removed from the funnel, placed in a dish, and moistened with very dilute hydrochloric acid, so that there is a slight excess of the latter. When solution has taken place, the paper is squeezed out with a glass rod and the liquid poured into a small filter. The paper which has been squeezed is washed twice with water, which is afterwards used to wash the second filter. There is thus obtained a liquid slightly coloured of a reddish-yellow, which is decolorised in the manner indicated above,—that is to say, by adding dilute ammonia until a white cloud begins to appear. If this latter does not disappear on agitation, a few drops of acidulated water are poured in, so as to keep the precipitate of a dark red colour. It is then to be filtered, the filter washed with a little distilled water, and ammonia poured into the clear and colourless liquid, so as to precipitate the quinine. This latter is collected on a paper filter, washed with distilled water, and dried in the air. When dry it is easily detached from the paper. The weight is then taken, which shows the richness of the bark.

Ten grammes of dull Calissaya quinquina should yield 30 to 32 centigrammes of white quinine, containing a very small quantity of cinchonine, which may be isolated with rectified ether.

Red quinquinas vary much. Whilst some very dense, bright, red barks have yielded me 0.33 grammes of a mixture of quinine and cinchonine from 10 grammes, others of a good appearance have only yielded 0.24 grammes when working on the same quantities.

Gray quinquinas have yielded me 0.10 grammes to 0.20 grammes of cinchonine when operating upon 40 grammes of bark; this gives the proportion between the cinchonine and the bark of 5 to 1000.

I have decided upon the treatment in the cold and by displacement to exhaust the barks because it is the method which has succeeded best with me. Decoction in acidulated water gives a liquid much changed with colouring matters. When caustic soda is added to this, the precipitate remains of a red colour, the filtration takes place with extreme slowness, and less product is finally obtained.

I have exhausted quinquinas with alcohol of various strength. I have added water to the alcoholic liquid, evaporated off the alcohol, and then added caustic soda to the residue. As with the liquids obtained by decoction the precipitate of quinine was mixed with colouring matter, the filtration was difficult and the product less abundant.

I prefer, therefore, the treatment in the cold, which gives real and positive reactions. When a little skill is acquired in this process, the assay of a quinquina will only be found to occupy about an hour's work.—*Journal de Pharmacie et de Chimie.*

On the Deleterious Effect of Light on Potatoes.

THE influence of light on vegetation is now regarded as a matter of the utmost importance, and although the precise mode of action may not be always understood, yet powerful effects of it are everywhere perceptible. In its absence leaves become blanched that would otherwise be green. Roots that are white underground become

green when exposed. Turnips, white beneath, are green or perhaps red above, and many kinds of fruit, naturally pale, colour under bright sunlight. By the action of light on leaves, the different secretions peculiar to plants are formed, such as gum, sugar, starch, oils, and even, in certain kinds of plants, deadly poisons. In some plants, too, the secretions due to the action of light are in certain portions harmless and nutritious, whilst in other parts of the same plant, through the same agency, highly deleterious principles are formed. The potato offers an example. Everybody knows that its tubers contain wholesome food, and it is also generally known that the stems, and especially the apples or seed vessels, are deleterious. But the treatment to which the potato is sometimes subjected is calculated to develop the poisonous quality in the tubers themselves, a change which can only take place during exposure to light. The poison found in the green parts of potatoes is called "solanine." This exists in several species of *Solanum*, and is found in considerable quantity in the shoots of potatoes. To obtain it the shoots are bruised and acted on by water acidulated with sulphuric acid. It is very poisonous. (Turner's "Elements of Chemistry.") Liebig says it is a powerful poison.

Although the stems of potatoes, according to the authorities just quoted, contain in notable quantity the noxious and easily-extracted principle, so dangerous in its concentrated form, yet the tubers grown underground and kept in the dark are floury and white when cooked, if the variety of potato is good, and quite free from acrid taste, which is one of the characteristics of solanine, and a sure indication of its presence. But the potato tuber is in reality a sort of stem; for it is furnished with buds, which, under favourable circumstances, push into shoots, as buds do on stems above ground. It is therefore, highly susceptible of the influence of light; for although both its skin and flesh are white, they soon become green by exposure; and the continued presence of light renders them as green as stems above ground. It is said that pigs have been killed by giving them potatoes greened to this extent. Such, of course, could not be sold for human food. For this purpose potatoes exposed to light must be housed or otherwise shaded before the green tinge is apparent, at least to the naked eye. But under the impression that the tubers keep better after having well basked in the sun, many cultivators are in the habit of turning them up, and spreading them out on the surface of the ground in bright sunny weather. This has the effect of greatly deteriorating their quality. Notwithstanding disease, really good potatoes can be found; but even slightly diseased ones, with the infected portions cut away, are infinitely better than quantities of others which, though they have a goodly appearance, have been greened. Instead of being white and floury when cooked, they are yellow, and have a disagreeable acrid taste, which can scarcely be disguised, or, if it should, there is no proof that the deleterious effects of the acrid principle are counteracted. At all events, it would certainly be very desirable that such means should be adopted as would prevent that principle being generated, or, in other words, the tubers should be kept as much as possible in the dark instead of exposing them to light. The advantage of exposure as regards better keeping is doubtful, whereas the deterioration it occasions in the quality of the tubers as an article of food is certain. I have thus endeavoured to draw attention to the subject, and it is the duty of every one who is aware of the deleterious effects of light on the potato to explain it to those who are not; for a knowledge

of it, if acted upon, would prove beneficial to both rich and poor.—*The Gardener's Chronicle and Agricultural Gazette.*

PHYSICAL SCIENCE.

On Spectrum Analysis, by Dr. K. M. GILTAY, Director of the Société Batave of Rotterdam. (Extract from a Letter to the Abbé Moigno.)

I READ in the *Cosmos* of September 13, that MM. Bunsen and Kirchhoff are blamed for not having mentioned M. Plucker as their forerunner in spectrum analysis. Not only do I perfectly agree with you, but, in my opinion, this is their least fault. M. Plucker has taken a great step further which they have entirely overlooked, and which is of great consequence in the explanation of these phenomena, perhaps also to the conclusions to be drawn from them.

M. Plucker has proved by vigorous experiments that the spectra of incandescent gases (simple or compound) are formed by luminous bands of an obscure background; that by properly narrowing the slit these bands can always be decomposed into bands of the same width as the slit; that there are no smaller ones¹; and that consequently these bands are formed by the homogeneous light, of which the index of refraction may be measured by determining that of the centre of the band; and that, strictly speaking, they may be broader than the slit, and the light is then of a continuous refrangibility, between the limits of dispersion of the extreme rays of the band. These larger bands may then form a considerable proportion of the entire spectrum. M. Plucker has measured, not only the index of refraction of these bands, but the length of the wave, so as to render the measurements wholly independent of the prism. In discussing the results, M. Plucker states his opinion that Fraunhofer's lines were not to be compared with these luminous bands, on account of the small diameter of the lines, almost innumerable in the spectrum which Fraunhofer, and after him Baden Powell and Brewster, have produced with a good sized slit. These lines of Fraunhofer's are, then, obscure lines on a luminous background. They are the particular lines wanting in a continuous spectrum. In Plucker's spectra, on the contrary, the bands are of homogeneous light on a dark background. These are the spectra of discontinuous refrangibility.

In their spectrum analyses, MM. Bunsen and Kirchhoff have made no strict measurements. They give the position of the lines only in relation to the solar spectrum by comparing the luminous rays of their spectra with Fraunhofer's obscure lines. I have repeated their experiments, and I can affirm that their conclusions are not a legitimate interpretation of the phenomenon. The luminous bands of different spectra are for the most part bands of homogeneous light, having the same breadth as the slit when they are properly contracted; if enlarged they are superposed. The calcium spectra gives the result admirably. The bands of lithium and potassium

¹ We believe that M. Plucker regards as an exception to the general rule the instance in which in the light examined by the prism there are solid and incandescent particles, which are all drawn in one common direction. The light being near the slit, there should be, besides the spectrum of the light, the spectrum of the minute, infinitely narrow line described by the incandescent particle, and seen across the slit. We adduce, as an example, the magnificent spectrum obtained by the prismatic analysis of the interior of the small flame obtained by burning ordinary lighting gas with the aid of a jet of oxygen gas.

being far apart, either do not give this superposition or give it very imperfectly. But it is chiefly by the aid of these spectra that we can demonstrate that the bands are always the same width as the slit. I repeated these experiments with one of Babinet's goniometers, and with a slit varying from 3' to 45'. In the calcium, strontium, and barium spectra there are bands somewhat wider than the slit, but, as M. Plucker says, the explanation of this is not difficult. Thus, these bands are not to be compared to Fraunhofer's lines.

So much for the facts; now for the consequences. MM. Bunsen and Kirchhoff have pointed out these spectra, first, as the best, or at least the most sensitive, means of chemical analysis. This is perfectly correct; but M. Plucker has said it before them, and you have proved it. Second, as a means of discovering the elements of the celestial bodies. They start with the law discovered (?) by M. Kirchhoff, that incandescent gases absorb instead of transmitting the rays which they emit. By superposing the solar spectrum, made sufficiently intense, upon the spectra of artificial lights, they found that some of these luminous bands became obscure. These were the bands coinciding (?) with certain lines of Fraunhofer. From this they concluded that the solar atmosphere gives a spectrum the inverse of what it would have given had it been the only luminous body; that this solar atmosphere contains the elements which give these characteristic bands, which become obscure by superposition.

Does not this conclusion require extreme circumspection, since it has not been proved that these luminous bands and Fraunhofer's lines are comparable? In the spectra of MM. Bunsen and Kirchhoff each band is only the length of a wave; each of Fraunhofer's lines, however fine it may be, has an infinity of them. That the luminous band should become obscure, the solar spectrum being superimposed, is very simple, since with a light so intense the rays of an isolated refrangibility, without the neighbouring rays of refrangibility to the right and left, would become very dark.

Allow me to remind you of Forbes' experiments, by which he proved that Fraunhofer's lines do not become darker during a total eclipse—that is to say, when the rays coming from the edge of the sun have to traverse a thicker solar atmosphere. This is, however, what must take place according to the hypothesis of MM. Bunsen and Kirchhoff. This is a little hasty (see your *Optique Moderne*), but it is worth discussing in relation to the other conclusions.

Has it not been observed that Fraunhofer's lines are less obscure at a great height above the level of the sea, and even that some of them are missing? This has caused their absorption to be attributed, at least in part, to our atmosphere.

Finally, one definite substance can perfectly absorb rays of different refrangibilities, as is proved by the spectrum of a luminous ray which has passed through certain gaseous bodies, nitrous acid, iodine, bromine, &c.—*Cosmos*.

PROCEEDINGS OF SOCIETIES.

PHARMACEUTICAL SOCIETY.

Wednesday, December 4, 1861.

Mr. P. SQUIRE, President, in the Chair.

THE adjourned discussion on the *Preparation of Extracts* was re-opened by the Chairman, who deprecated any

departure from the directions of the Pharmacopœia which the previous discussion might be supposed to justify. He acquitted the compilers of the Pharmacopœia of ignorance. They did not consult the makers of extracts; and the makers did not know that they produced a better article than could have been made if the directions of the Pharmacopœia had been followed. That book was compiled by the highest scientific authorities in the country; but, until now, practical pharmacutists had not been consulted. A delegate from the Pharmaceutical Society was now, however, assisting in the preparation of the British Pharmacopœia, and pharmacutists had the opportunity of conveying information to the authors. When, therefore, the work is constructed, it will be the duty of pharmacutists to implicitly follow its directions. The Chairman then quoted the processes for the preparation of extract of belladonna given in several foreign Pharmacopœias. The French Codex was not quoted, the last edition having appeared twenty-five years ago, and a new one being now in progress. The Prussian Pharmacopœia, used in Germany and Switzerland, ordered the leaves, stem, and flowering branches to be taken, moistened with one-third the weight of water, pressed, strained, and evaporated, filtering at a certain stage to get rid of the chlorophyll. A dry extract was also ordered to be made by taking a certain amount of the moist, drying it, and then mixing sufficient sugar of milk to make up the original weight. The Belgian Pharmacopœia of 1854 directs the flowering herb to be used. The Norwegian Pharmacopœia, published last year, orders the extract to be made from the powdered dried leaves. The process of the American of 1855 is the same as our own. The Chairman then gave a *résumé* of the previous discussion; the tendency of which, he said, was to support the use of all the soft parts of the plant in making the extract.

Professor REDWOOD said the subject under discussion was a very interesting one as well as of considerable importance. While admitting that at the last meeting (which illness had prevented him from attending) it had been most fully and well discussed, he felt very dissatisfied with the results in two or three respects. In the first place, he thought the general tone of that discussion was to weaken the authority of the Pharmacopœia, and encourage pharmacutists to deviate from its directions. The Chairman had cleared up this point in his opening speech, and nothing further need be said on that part of the subject. The Professor then called on the Chairman to describe more particularly the parts of the plant used in the preparation of the extract said in the paper to be the strongest and best. Was it really made from stalks, or partly from flower and fruit? From the report of the last meeting it would certainly appear that the stronger extract was made from stalks, and, therefore, the manufacturers would reserve the leaves for purposes to which the stalks were not applicable, and extracts would be made from these and nothing else. The tendency of the foreign Pharmacopœias, the Professor said, was to deviate from the process received as the best in this country, and to reject the albuminous matter and chlorophyll. Extracts made in this way would keep good an indefinite time. Mr. Scanlan had pointed out twenty years ago that the mouldiness of extracts was due to the albumen, take that out and the extract will keep.

THE CHAIRMAN, in reply, said that no manufacturer would think of using the thick, hard stalks of plants for making extracts, and his paper indicated that large stalks were not to be used. The Pharmacopœia directed the extract of belladonna to be made from leaves only: he had taken the rejected "soft parts," and had prepared an extract which was one-fourth stronger. By "soft parts" he did not mean the thick, hard stalks. His meaning was well given by Mr. Holland in the last discussion, who said he used all the soft parts "which could be easily broken by the hand."

A long conversation followed, in which, however, nothing of novelty or interest was elicited, and the meeting adjourned, the other papers announced being postponed until the next.

MANCHESTER

LITERARY AND PHILOSOPHICAL SOCIETY.

Ordinary Meeting, November 26, 1861.

J. P. JOULE, LL.D., President, in the Chair.

Mr. JOSEPH SIDEBOTHAM exhibited a photograph of the contorted schists seen in the cliff near the South Stack Lighthouse, Holyhead.

Mr. JOHN PARRY showed some photographs of fossil woods from the South Lancashire coal field. These displayed beautifully the structure, even to the most minute vessels.

A Paper was read by Mr. E. W. BINNEY, F.R.S., Vice-President, entitled "*Additional Observations on the Permian Beds of South Lancashire.*" This was a continuation of two previous papers read before the Society and printed in its Memoirs.¹ Since that time the author had made further observations on the Permian strata at Heaton Norris, near Stockport; Medlock Vale, between Ashton and Manchester; Chorlton-upon-Medlock, and Ordsal, near Manchester; and Skillaw Clough and Bentley Brook, near Newburgh, in the West of Lancashire.

At Heaton Norris, in the sand delf of Mr. Howard, near the railway station, the lower new red sandstone was seen dipping to the south-west at an angle of 25°. This was succeeded by red and variegated marls having a similar dip. These last named strata were overlapped by the Trias, which dips to the south-west at an angle of 12°.

At Heaton Mersey the following section was met with:

	Feet.
Trias.	45
Permian—Red and variegated marls containing lime-stones	9
Lower new red sandstone grooved	402

The Permian beds were cut off by a fault near the railway station at Heaton Norris, first shown to me by Mr. Hull, B.A., F.G.S., of the Geological Survey, which brought in the Trias. This rock occupied the district between that town and Goyt's Hall, in the Marple valley, where the lower part of the middle coal measures was seen in a nearly vertical position.

The author considered that Mr. Howard's sand delf is a likely place for ascertaining the existence of a coal field under the town of Stockport worth working.

The next was a section made by Mr. John Wood, at Medlock Vale, between Waterhouses, near Ashton-under-Lyne, and Manchester. It was as follows:

	Feet.	In.
Drift	26	0
Trias	23	0
Permian—Red marls, with beds of limestone and five beds of gypsum.	246	3
Lower new red sandstone.	375	11
Coal measures	about 90	0

761 2

What these coal measures were, whether above or under the Bradford Four Feet Mine, it was at present impossible to say; but it was to be hoped that some mine would be met with to enable us to determine the value of the great tract of coal measures lying between Ashton-under-Lyne, Oldham, Middleton, and Manchester. Mr. Wood had done more than any other gentleman to clear up this point, and it was to be desired that he should meet with

a good seam of coal, both for his own sake and that of the public.

The third section mentioned was at the sugar works of Messrs. Fryer and Co., in Chester Street, Chorlton-on-Medlock, Manchester. The following beds were there met with.

	Feet.
Trias.	114
Permian—Red marls with limestones	237
Coarse red sandstone with pebbles	45
Coarse red sandstone.	24
Coal measures consisting of red shaly marls and limestones (Ardwick).	126

546

The limestones in the last named strata contained specimens of *microconchus carbonarius* and scales of *paleontiscus*, which clearly proved them to be similar beds to those of the upper coal field at Ardwick, to which they bear every resemblance in physical character.

The occurrence of coal measures on the south side of the city of Manchester is quite new and of great importance, showing that such strata at places are met with under permian and trias deposits much nearer the surface than was previously suspected, and where the upper rocks gave no evidence of their proximity. The above bore has proved beyond doubt that a band of coal measures lies under the south of Chorlton-on-Medlock, and possibly extends to Heaton Norris, being probably brought up by the great Pendleton fault, which most likely passes through the south of Manchester and joins the fault seen near the railway station at Heaton Norris previously alluded to, and described more fully in the Paper.

In the fourth section, at Ordsal, Messrs. Worrell found the trias beds 460 feet in thickness without going through them. At the bottom of the bore the water became so salt that they discontinued the work, it being no longer fit for dyeing and such like purposes. This is the first instance, to the author's knowledge, where salt water has been met with in the trias near Manchester.

The fifth and sixth sections were at Skillaw Clough and Bentley Brook, to the north of the Newburgh station on the Manchester and Southport Railway. These were some time since discovered by Mr. E. Hull, B.A., F.G.S., of the Geological Survey, and described shortly by that gentleman in the sheet explaining the map of the district. Further particulars were given of the details of both sections, and an analysis of the limestone was produced, which showed it to differ in its chemical characters from the thin ribbon bands found in the permian marls near Manchester, Patricroft, Astly, and Leigh, and was very like the yellow magnesian found at Stank, in Furness, North Lancashire. Probably it might prove to be a different bed, and more like the great central deposit of magnesian limestone of Yorkshire than the thin beds previously alluded to.

MICROSCOPICAL SECTION.

November 18, 1861.

E. W. BINNEY, F.R.S., F.G.S., in the Chair.

Dr. Edward Stephens was elected a member of the Section.

The SECRETARY read a communication from Mr. THOMAS G. RYLANDS, of Warrington, "*On the Classification of the Diatomaceae.*" The author desired to call attention to the want of systematic arrangement which characterises this favourite branch of microscopical investigation, and to the necessity of a thorough revision of the entire classification of the natural order. The author presented to the Section two slides to illustrate his arguments. The predominant form of frustules was first named by Dr. Brebisson *Cocconeis lavis*. In 1857 it was published by Mr. Roper (M. I. vol. vi. p. 22) under the provisional name *Cocconeis*.

¹ Vols. xii. and xiv. (New Series) of the Society's Memoirs.

discus ovalis; but in consequence of finding on the valves eight to twelve submarginal obtuse processes with tumid bases, quite distinct from the spines or teeth which occur in the *Coscinodiscæ*, the author considers this species must be placed in the genus *Eupodiscus*, and may fitly be called *Eupodiscus levis*. The specimens were obtained at Llandudno, in ripples in the sand below mid-water; and the Paper concludes with a description of some peculiarities connected with their sudden disappearance.

Mr. JOHN WATSON read a paper "On certain Scales of some Diurnal Lepidoptera," in which he recommends a new and careful study of this subject. In some genera peculiar scales, called plumules, have long been known; but examination with the binocular microscope shows that they are not flat like the ordinary scales, but cylindrical and hollow. They have been found only in certain genera (named in the paper) at present, and on the males alone; they possess generic resemblances and specific differences, each species displaying its own distinguishing variety. One of great beauty and novelty, found only on two African butterflies, *Pieris Agathina* and *Pieris Chloris*, was described, and some very fine drawings of it, by Mr. Joseph Sidebotham, were exhibited, and also other figures by him of about one hundred species never figured before. The names and habitats of the insects were given, and the author pointed out the value of these scales for the assistance of the scientific entomologist in arranging genera and species; he then entered into the question of their probable use as air vessels in the economy of the insects possessing them.

The CHAIRMAN remarked that the scales of the Lepidoptera may prove to be as valuable in determining species as the scales of fishes.

Mr. SIDEBOTHAM alluded to the value of the binocular microscope in defining the cylindrical form of the plumules, and described the mode of finding them *in situ*, by breaking the wing.

Mr. WATSON stated that some of Mr. Sidebotham's excellent drawings were taken under the eighth objective, magnifying 750 diameters. Mr. Watson further said that he had examined the wings of 400 specimens of the *Papilionidæ*, but had not discovered any plumules in that genera; he also alluded to several so called species from South America, of which no males have yet been found, others of which no females have yet been discovered, and suggested the possibility of some of these being male and female of the same species; to ascertain which, careful examination of the scales might be useful.

Mr. WATSON exhibited a number of mounted specimens of the plumules, and four cases of the Lepidoptera from whose wings the 98 drawings figured by Mr. Sidebotham were taken. They were principally *Pieris*, *Anthocaris*, *Thestias*, *Euterpe*, and *Eronia*; amongst the former were some new and unnamed species from Celebes, with rare specimens from Venezuela, Quito, East and West Indies, Africa, and other parts of the world.

Mr. DALE placed on the table a number of washed soundings, of which several members took specimens for examination.

Mr. DALE also reported that the sulphate of copper and magnesia has been long known to be a compound salt. When the magnesian salt is in excess, it has seven equivalents of water; and when the copper salt is in excess, it has five equivalents of water. Mr. Dale has also made for the occasion samples of the double sulphate of copper and potash, the double sulphate of copper and ammonia, and the double chloride of copper and ammonia, which he distributed amongst the members. They were all beautiful polariscopic crystals, the chloride particularly so, and each has its characteristic form.

Mr. LINTON exhibited the hairs on the *Loasa Coccinea* (Chili nettle), mounted by Mr. Heys.

Mr. DANCER exhibited a specimen of the *Aulocadiscus formosus*, which in consequence of a fracture since it was

mounted, shows more distinctly the form of the projections that Mr. Sidebotham brought under the notice of the Section at the last meeting. These handle-shaped spines Mr. Dancer observed, when seen with the one-eighth power and binocular microscope, are found to project outwards from each of the four elevations on the surface of the valve.

Mr. BROTHERS exhibited the *Floccularia ornata*, and a fine group of *Lacinularia socialis*.

Mr. MOSLEY exhibited a specimen of *Amœba*, and described the peculiarity of its motion. He had observed one of them rise in a straight line four-fifths of its entire length, its internal particles appearing to force outwards a transparent or invisible integument; the point then fell over, forming an arch, after which it subsided into the common three or four-lobed form. In many specimens no vacuole was observed; in others, an apparent air or water space was noticed. A portion of the one under examination appeared to be blown outwards like a bladder, in which appeared a small animalcule making desperate efforts to escape. The best illumination for observing the internal motion, he considers to be Wenham's parabola and Lieberkühn, with a four-tenth objective.

NOTICES OF PATENTS.

769. *The Preparation of Hydrated Oxide of Iron, and the Application of such Prepared Oxide for the Absorption or Separation of Sulphur from Certain Gases.* J. G. WILLIAMS, Belfast. Dated March 27, 1861.

ACCORDING to this invention the brown hæmatite, or other natural form of hydrated oxide of iron, is reduced to fine powder by grinding under mill-stones, the small particles are then separated from the coarser, either by sifting, or by means of currents of air, or water, when a material is obtained admirably adapted for absorbing the sulphuretted hydrogen from foul coal gas and other gaseous mixtures containing it. The second part of the invention relates to the treatment of sundry ferruginous products, such as roasted pyrites, forge cinder, hammer scale, and furnace slags, containing not less than 30 per cent. of iron, which are to be subjected to heat in contact with carbon, or any appropriate deoxidising agent, with the intention of producing a crude kind of metallic iron, and afterwards leaving this exposed to the rusting influence of air and moisture, to obtain a partially oxidised material well calculated to retain the sulphuretted impurities of common coal gas.

This proposal appears likely to be serviceably employed in the preparation of ochrey iron ore, and other forms of hydrated oxide which occur not only in Ireland, but away from coal, and hence comparatively valueless in some parts of England. A mixture of sulphate of iron, lime, and sawdust (really equivalent to hydrated oxide of iron), has formed the subject of more than one patent claim for a similar application. The ochrey ironstone of Oxfordshire has also been employed for the purification of gas.

775. *Brewing.* L. J. VANDECASTELLE, Lille, France. Dated March 28, 1861.

THE improvements comprehended in the specification refer to the employment of lime in the mash tub, for the purpose of more thoroughly removing the suspended impurities from the wort. After clarifying in this manner, the excess of lime is precipitated from the beer by passing a current of carbonic acid gas, using for this purpose a perforated worm tube.

Ordinary beer holds in solution a large proportion of earthy phosphates, which would, no doubt, be partially removed by the addition of lime. It is a serious consideration whether perchance so dark coloured a beverage might

not sometimes disguise the presence of carbonate of lime particles, held in suspension in the beer, the administration of which to the human digestive system might be attended with dangerous consequences.

Grants of Provisional Protection for Six Months.

2750. William Bickford Smith, Camborne, and William Bennetts, Tuckingmill, Cornwall, "Improvements in the method of, and apparatus for, preventing the injurious effects occasioned by smoke, sulphur, and the deleterious gases which escape from stacks, chimneys, calcining houses, chemical and other furnaces."—Petitions recorded November 1, 1861.

2790. Frederick George Stuber, St. James's-road, Brixton, Surrey, "An improved hygrometer for measuring the humidity of the atmosphere, dampness of beds, garments, and for other similar purposes."—Petition recorded November 6, 1861.

2864. John Leslie, Esq., Conduit Street, Hanover Square, London, "Improvements in the manufacture of gas."—Petitions recorded November 13, 1861.

2900. George Parry, Ebbw Vale Ironworks, Monmouth, "Improvements in the manufacture of iron and steel."—Petitions recorded November 18, 1861.

Notices to Proceed.

1863. William Longmaid, Inver, Galway, Ireland, "Improvements in the manufacture of iron."—Petitions recorded July 24, 1861.

1869. Edward Haefely, Kearsley, Lancashire, "Improvements in extracting copper from its ores."—Petition recorded July 25, 1861.

2001. Antoine Garzand, Boulevard St. Martin, Paris, "A new or improved apparatus for cutting up and reducing dye and other wood."—Petition recorded August 12, 1861.

2031. John Bethell, King William Street, London, "Improvements in the manufacture from steatite of journals, axle-boxes, and bearings for machinery, axles, and spindles to work in, smoking pipes, buttons, crucibles, and pots, for chemical and smelting purposes, and also of a lubricating compound for railway and other carriages."—Petition recorded August 15, 1861.

2618. Frederick John Evans, Gas Works, Horseferry Road, Westminster, "An improved mode of, and apparatus for, carburetting gases for the purpose of illumination."—Petition recorded October 19, 1861.

CORRESPONDENCE.

On the Chemico-Microscopical Characters of Beef and other Fatty Matters.

To the Editor of the CHEMICAL NEWS.

SIR,—Following out my experiments on fatty matters, as suggested in my paper contained in your last impression, I find that beef dripping treated with benzole, and then with ammonia, assumes under the microscope a similar character to that of butter, with this difference, that the crystals of beef fat are more strongly marked and of greater angular divergence, whilst the uncrystallizable portions are more opaque than those of butter. There is a striking difference, however, in their solutions in ether by which any adulteration is clearly indicated. Beef fat depositing considerably after a time, but butter as before observed is entirely and permanently soluble at 65° and it is only at about 52° or 53° that anything falls when masses of beautiful velvety crystals not unlike benzoic acid form; mutton dripping similarly treated is of a firmer and waxy like character, and under the microscope does not show any tendency to crystallization, being in the form of transparent layers or plates, and deposits from its ethereal solution in a closer and more granular form than beef dripping.

These are all the observations I have thought necessary to complete the subject. No doubt Anatomists and Physiologists will find the microscopic method I have suggested of some value in their researches.

The crystals I speak of are probably those of margarine, being when broken in plumose tufts or brushes, but when whole in the stellar form, the long needle points radiating from one common centre. They are smallish in cow fat, i.e., butter, ox fat being, as before observed, similar but larger; mutton fat being nearly all stearin, while lard consists principally of olein and stearin, with comparatively very little margarine; hence its unctuousity and apparent indisposition to crystallise.

I am, &c., JOHN HORSLEY,
County Analyst's Laboratory, Police-Station, Cheltenham.

Chemical Nomenclature.

To the Editor of the CHEMICAL NEWS.

SIR,—Will you allow me to make a few observations in reply to Mr. McLeod's remarks on my new system of nomenclature?

Mr. McLeod objects to my system because of the complicated names to which it leads, though, at the same time, the longest of these is not a quarter the length of those he himself proposes.

None of the names which I have hitherto constructed from empirical formulæ are more than four syllables in length; the greater part are composed of two or three syllables,—so much for the charge of complexity.

I subjoin the names of a few bodies taken at random:—

Citric acid	$C_6H_8O_7$	kamlatic acid
Tannic acid	$C_{12}H_{10}O_{11}$	gremfetic acid
Benzoic acid	$C_7H_6O_2$	lakdatic acid
Salicylic acid	$C_7H_6O_3$	lakfatic acid
Gallic acid	$C_7H_6O_5$	lakhatic acid
Amygdalin	$C_{20}H_{27}NO_{11}$	chetranine
Harmaline	$C_{15}H_{15}N_2O$	tarbanamine
Harmine	$C_{15}H_{15}N_2O$	taabanamine
Aconitine	$C_{34}H_{47}NO_7$	slolhanine
Morphine	$C_{17}H_{19}NO_3$	zehfanine

Mr. McLeod disposes of my system in a very summary manner. After having said that it was similar to those of Gmelin and others, he thinks that my name "for acetic acid (dagdatic acid) is not much simpler than Gmelin's term for alcohol (linavinam)," and he therefore condemns both.

By what peculiar process of oxidation or reduction Mr. McLeod was led to compare my name for acetic acid with Gmelin's for alcohol, I cannot for a moment conceive, and am equally at a loss to understand why, upon the ground of the one name not being much simpler than the other, he concludes that my system "has no chance of being adopted."

The names assigned by me to acetic acid, and ethylic alcohol, are dagdatic acid and dakkatic alcohol, both of which are as short and simple as those now in use, besides having the great advantage of expressing the formulæ of the bodies in question.

Gmelin furnishes names for all substances whatever; I restrict myself to what are commonly called organic bodies, for, as carbon, hydrogen, and oxygen appear to possess extraordinary faculties of entering into combination, the compounds of these elements require a special nomenclature of their own.

The systems of Gmelin, Laurent, and others, require long study before they can be comprehended, let alone made use of; mine, on the other hand, is very brief, easy to be understood, and can be at once turned to practical account, even if it be only as an aid to the memory.

Gmelin's names are lengthy, very unmusical, difficult to pronounce, and utterly unlike those at present employed, which, moreover, they were intended to supersede. Mine,

on the contrary, are short, possessed of considerable euphony, very like those at present employed, and may be either used in conjunction with these, or *per se*.

The plan of naming a body by enumerating all the radicals it contains, or is supposed to contain, must infallibly lead to names of great length; but, since this appears to be quite the fashion, it is a great pity that the names of these radicals do not give us the least idea of their composition.

The following are a few of the radicals named after my method:—

Methyl CH_3 bafyl	Phenyl C_6H_5 kahyl
Ethyl C_2H_5 dahyl	Ethylene C_2H_4 dagyl
Propyl C_3H_7 fahyl	Glyceryl C_3H_7 fahyl
Butyl C_4H_9 gahyl	Acetyl $\text{C}_2\text{H}_3\text{O}$ dasfayl
Amyl C_5H_{11} hahyl	Benzoyl $\text{C}_7\text{H}_5\text{O}$ lahbayl
Caproyl C_6H_{13} kahyl	&c. &c. &c.
C_7H_{15} lehyl	
C_8H_{17} mehyl	
C_9H_{19} nehyl	

Are not these terms "short, concise, and expressive"? Mr. McLeod says that, "if a nomenclature that would not interfere with the designation of the derivatives of ammonia could be found, it would stand more chance of adoption." To this I answer that my system does not interfere with the method at present employed in naming these compounds, except so far as the radicals they contain are concerned; for instance, I call

Methyl-ethyl-amyl-phenyl-ammonium,
Bafyl-dahyl-haryl-kahyl-ammonium;

the only difference being that the names methyl, ethyl, &c., indicate nothing, whereas bafyl is CH_3 , dahyl C_2H_5 , haryl C_3H_7 , and kahyl C_6H_5 .

I have indeed employed certain syllables to indicate the amount of nitrogen in a substance when its nature was not thoroughly understood; thus, I have called morphine sehfanine, expressive of the formula $\text{C}_{17}\text{H}_{19}\text{NO}_5$; but, by and by, when the radicals which enter into the composition of this alkali are better known, we shall be able to construct a name for it five or six times as long as the preceding, and one which will therefore, no doubt, "stand more chance of adoption."

Empirical names may of course be framed for the compound ammonias, such as

Methylethylamylamine	$\text{C}_9\text{H}_{17}\text{N}$ mehnine,
Ethylamylamine	$\text{C}_{13}\text{H}_{27}\text{N}$ telnine, and
Methylethylamylphenylammonium	$\text{C}_{14}\text{H}_{21}\text{N}$ vepnine.

But I do not advocate the use of such terms except under certain conditions, though I conceive that empirical names are at least as useful as empirical formulæ, and that all the arguments of Laurent and others in support of the one may be adduced with equal force in behalf of the other.

An "Inquirer" desires to know what name I give to albumen. My reply is that, when the formula of albumen is established beyond a doubt, it will be time enough to think of constructing a name expressive of its composition; but, whether a new appellation be devised or not, I would always retain the name of albumen, my desire being to preserve, as far as possible, names which are associated with the labours of illustrious men, which we have long been accustomed to pronounce, and which have become "familiar in our mouths as household words."—I am, &c.

JOHN A. R. NEWLANDS, F.C.S.

Chemical Notices from Foreign Sources.

I. GENERAL CHEMISTRY.

Compounds of Two Acids.—M. Schutzenberger announced some time ago, the formation of a compound of anhydrous sulphuric and anhydrous hypochlorous acids (CHEMICAL NEWS, vol. iii. p. 226). He has now (*Comptes-Rendus*, t. liii. p. 532) ascertained by analysis the exact

proportions in which the acids had united. The compound is obtained by passing a current of hypochlorous acid over the anhydrous sulphuric. As soon as the two acids come in contact, the sulphuric liquefies, becomes hot, and takes a deep red colour. The product is thick, and on cooling soon solidifies to a mass of bright red acicular crystals very like chromic acid. These fuse about 55°C , and are immediately decomposed by water into hydrated sulphuric and hypochlorous acids. Organic matters such as sugar and alcohol, reduce the compound producing incandescence, iodine acts on it violently disengaging chlorine and forming iodic acid; in a word, it behaves as an energetic oxidiser. Heated quickly it detonates. By saturating it very carefully with pure potash, dividing the solution into two equal parts, estimating the chlorine in one and the sulphuric acid in the other, the author came to the conclusion that it was a compound of 4SO_2 and ClO .

Hypochlorous acid gas passed into liquid sulphurous acid sets up a lively reaction; chlorine is evolved and there remains in the receiver a thick red liquid which contains both acids, but in what proportions the author has not yet determined.

Acetic and Arsenious Acids unite in equivalent proportions when boiled together. The product is a thick, colourless, syrupy body, which on cooling becomes vitreous and quickly attracts moisture. Water instantly decomposes it into the two acids. About 220°C . it evolves a good deal of carbonic acid and traces of arseniuretted hydrogen, hydrated acetic acid passing off at the same time and leaving a residue of metallic arsenic. The new compound is an acetate of arsenious acid: $\text{C}_4\text{H}_5\text{O}_3$, As O_3 .

Acetic and Boracic Acids in the anhydrous state behave like the two former, but the solution takes place slower. The compound obtained is also a vitreous mass decomposable by water. By dry distillation the acetic acid is separated, and a reddish brown residue remains which contains all the boracic acid used. Like the above the compound of the two acids will no doubt have the formula $\text{C}_4\text{H}_5\text{O}_3$, Bo O_3 .

Acetic and Tartaric Acids when boiled together form a thick, yellowish, syrupy liquid which begins to decompose at about 130°C , evolving a mixture of carbonic acid and carbonic oxide, the volume of the former a little exceeding that of the latter.

The same compound is formed by the action of chloride of acetyl on tartrate of lead, chloride of lead being also produced. This leads to the formula $\text{C}_8\text{H}_4\text{O}_{10} \cdot 2(\text{C}_4\text{H}_5\text{O}_3)$.

Acetic and Sulphuric Acids. When anhydrous acetic acid is properly cooled it absorbs vapours of anhydrous sulphuric acid, forming a yellowish, gummy mass, which is soluble in water. The solution saturated with baryta water and separated by filtration from the sulphate of baryta, yields crystals having the characters and composition of sulphoacetate of baryta. It follows that by the direct action of the two acids there is formed anhydrous sulphoacetic acid, or the anhydrous bisulphate of the oxide of acetyl, 2SO_3 , $\text{C}_4\text{H}_5\text{O}_3$.

Action of Perchloride of Phosphorus on Several Elements.—M. E. Baudrimont has made a long series of experiments, from the results of which he draws the following general conclusions. (*Comptes-Rendus*, t. liii. p. 637.) 1. The metalloids exert a more varied action on perchloride of phosphorus than the metals. 2. Oxygen forming a chloroxide of phosphorus presents a remarkable case of the substitution of this gas for chlorine. 3. Sulphur and selenium do not act in the same way. Sulphur gives compounds of PCl_3 and S_2Cl_2 . Selenium forms protochloride of phosphorus and protochloride of selenium, both free. Further, selenium does not form a chloroselenide of phosphorus, but a compound of PCl_3 with PCl_3 may be obtained. 4. Iodine acts on PCl_3 and forms ICl , which combines with the excess of PCl_3 to produce the compound $\text{PCl}_3 \cdot \text{ICl}$. 5. Metals, by simple mixture,

at a temperature short of volatilising the PCl_5 form protochloride of phosphorus and metallic chlorides, which mostly unite with the excess of PCl_5 to produce double chlorides. This is the case with aluminium, iron, tin, bismuth, platinum, and perhaps zinc and copper. 6. When the metal is red hot, the "dechloruration" is more complete, and free phosphorus is obtained, which in some cases combines with an excess of the metal and forms metallic phosphides. 7. When the phosphorus becomes free it is always at the expense of the PCl_5 first formed and then decomposed. 8. Gold and platinum are acted on by perchloride of phosphorus, the latter metal most easily. 9. Of all metals antimony is the most easily acted on. 10. In all these reactions, the perchloride may be considered to act like strongly condensed chlorine, and the action seems to be greatly facilitated by the tendency which the PCl_5 has to unite with most of the chlorides to which it gives rise.

II. ORGANIC CHEMISTRY.

Compound of Aldehyde and Oxide of Ethylene.

—Wurtz (*Comptes-Rendus*, t. liii. p. 378) formed a compound of the above by heating aldehyde and an excess of glycol together for eight days. The experiment was made with the view of ascertaining whether the two would combine to form bodies isomeric with the polyethylenic alcohols formed directly by the union of oxide of ethylene with glycol. The two did combine, but the author found a new compound having the formula $\text{C}_4\text{H}_8\text{O}_3$, showing the unexpected result that the aldehyde dehydrated the glycol and combined with the oxide of ethylene so produced. The new body is a colourless liquid, having an agreeable odour; the density at $0^\circ = 1.0002$; the boiling point 82.5°C . It is soluble in $\frac{1}{2}$ times its volume of water, but chloride of calcium and potash separate it from the solution. Nitric acid acts on it violently, forming, among other products, glycolic and oxalic acids. It is not affected by caustic potash; at 100°C . it reduces partially and slowly an ammoniacal solution of nitrate of silver.

The author found that aldehyde and oxide of ethylene would not combine when heated together for several days. The aldehyde became resinified, and the oxide of ethylene remained unchanged.

The Formation of Oil in Olives.—M. S. de Luca has made an important series of observations on this subject (*Comptes-Rendus*, t. liii. p. 386). His object was to ascertain at what stage of the growth the fatty matter began to form, and what matter or matters preceded and gave birth to the oil. He found that a very young olive had the density 1.008, and that from this it slowly increased until the density reached 1.097. From this point, as the oil was formed, the density diminished, and the author found a perfectly ripe olive to have the specific gravity 1.007. Perhaps the most important point determined by the author was the presence of mannite, which, he says, appears to be essential to the formation of the fatty matter. The human physiologist may perhaps take a note of this fact. A peculiar bitter principle was also found in the green olives, which the author could not isolate. Like the mannite, it is also to be found in the leaves, which, perhaps in virtue thereof, appear to possess decided febrifuge properties.

Cinnamates and Nitro-cinnamates.—M. E. Kopp has prepared and described many of these (*Comptes-Rendus*, t. liii. p. 634). The general properties of the cinnamates he describes as follows:—Those with an alkaline base are soluble in water. The alkaline-earth salts are but slightly soluble in the cold, but more so when heated. The earthy salts are insoluble, and are partially decomposed by boiling water. The metallic salts are almost insoluble even in boiling water, but are in general dissolved on the addition of a little acetic acid.

Nitro-cinnamic, though a weak acid, forms neutral salts, and decomposes alkaline carbonates. The alkaline salts

are very soluble, the others are but slightly so, or are altogether insoluble. They all deflagrate when quickly heated.

Cinnamene, C_{10}H_8 , is not only isomeric but completely identical with styrol. When pure it will change spontaneously into metacinnamene perfectly solid, transparent, and having all the properties, chemical and optical, of metastyrol.

III. ANALYTICAL CHEMISTRY.

Separation of Natural and Artificial Camphor.

—We find the following in the *Archiv. für Pharmacie*, bd. clvi. s. 332. In an alcoholic solution of natural camphor ammonia gives but a slight precipitate which is redissolved on shaking the mixture. A similar solution of artificial camphor, under the like treatment, gives a flocculent precipitate which remains undissolved.

MISCELLANEOUS.

Royal Institution.—The following meetings will take place next week:—Thursday, December 26, at three o'clock, Professor Tyndall, "On Light" (juvenile lectures); Saturday, December 28, at three o'clock, Professor Tyndall, "On Light" (juvenile lectures).

An Appeal for the "American Journal of Science."—Professors Silliman and Dana, the proprietors and editors of the *American Journal of Science*, have issued the following appeal to their friends:—"Cut off by the exigencies of the times from a large number of our subscribers—residents in disloyal states, and participating in the inconveniences consequent on the general derangement of public affairs, the proprietors of this journal trust they may be permitted to express to their subscribers and to the friends of science generally the hope that they will in all cases renew and continue their subscriptions to the *American Journal of Science* for the ensuing year. Claiming the privilege of bearing cheerfully our share of the present demands on all patriotic citizens, our hope is to receive such a measure of co-operation from the friends of science as will enable us to sustain with credit the public trust so long, by their indulgence, committed to our hands. This co-operation we look for not only from those whose names have been long on our lists, but from many others also who may desire thus to testify their good-will to the cause we represent."

ANSWERS TO CORRESPONDENTS.

* * All Editorial Communications are to be addressed to the Editor; and Advertisements and Business Communications to the Publisher at the Office, 1, Wine Office Court, Fleet Street, London, E.C.

A Subscriber.—We will endeavour to ascertain.

C.R.—See Dr. Cattell's patent noticed in a previous number of the *CHEMICAL NEWS*.

Analyses of Yeast.—D. Clifton wishes to know where he can find Analyses of German dried yeast, and also Brewers' ale yeast.

O.—Noad's "Lectures on Electricity" is about as useful a book on the subject as can be placed in the hands of a person quite ignorant of the science.

M.D.—An electric light will have to be used, in order to throw metallic spectra on to a screen. The salts experimented upon must be placed in a small cavity bored out of the lower carbon pole, and the slit prism and lens must be arranged at such relative distances from each other and from the light, that a sharp image of the coloured bands is formed on the screen. This is not difficult to manage after a few trials, but it cannot be more fully explained without a diagram.

Iodide of Cadmium.—W.C.—The best way of preparing this salt is to take one part of cadmium in filings and two parts of pure iodine. Place them together in a capacious flask with a sufficient quantity of alcohol to cover them. Action will commence at once, attended with considerable evolution of heat. When the action ceases, heat the mixture till it is colourless. Filter from a few grains of cadmium, which will remain undissolved, evaporate, and crystallise.

SCIENTIFIC AND ANALYTICAL CHEMISTRY.

Researches on the Relations existing between Atomic Weights, by M. J. S. STAS, Member of the Royal Academy of Belgium.

(Continued from page 325.)

Analysis of Chlorate of Potash.—The determination of the oxygen contained in chlorate of potash has been made so often that it might be asked if there was any utility in repeating it. What has led me to undertake this analysis is, that the concordant results of Berzelius, M. Pelouze, and M. de Marignac disagree with those of M. Maumené and of M. Penny, to the accuracy of which I can certify. To perform this determination I made use of two different methods which ought to yield errors in opposite directions. My object in acting thus was to ascertain the extreme limits between which the figure would be found. One of the methods consists in decomposing the chlorate by heat, so as to weigh the residuary chloride: this is the process employed successively by Berzelius, Pelouze, De Marignac, and Maumené. The other consists in decomposing the chlorate with hydrochloric acid, and then weighing the residuary chloride; this is the plan adopted by Penny, but which I have modified in its details.

The chlorate experimented upon was prepared by the means which I pointed out when speaking of chloride of potassium obtained from the chlorate. I need not now return to the subject. I will only say, that I am sure it contains neither iron, manganese, copper, chloride, nor alkaline sulphates. I am, however, certain that it contains traces of silica, which it has not been in my power to separate from the salt without decomposing it.

I will now explain the arrangement which I made to perform the operation by each of these two methods.

Determination of the Oxygen in Chlorate of Potash by Decomposing the Salt by Heat.—I have performed five experiments by this method: two in a hard glass globe, of about two litres capacity, furnished with a neck 55 or 60 centimètres long and 2 centimètres wide: and three in a sphere of hard glass, with two necks opposite to each other, analogous to the apparatus employed by M. Dumas in his syntheses of water.

In the experiments with the simple globe I curved the neck at right angles as close as possible to the reservoir. To the end of this neck I fastened, by means of a resinous cement, a metallic cap, on which a stop-cock screwed. The complete apparatus held a vacuum perfectly. In the weighings I used as a counterpoise a globe of absolutely the same capacity and weight as the one used in the experiment, placing, at the same time, on the two pans of the balance a weight superior to that which I had to determine. I thus performed the successive weighings by subtraction. I placed the same supplementary weight

on each pan in order to remove any doubt about maintaining the quality of the arms of the balance during the successive weighings. The correction of the weight for the reduction to a vacuum was thus performed only upon the differences from the original weight,—differences which in this case corresponded to the weight of the substance.

When the equilibrium of the globe perfectly dry and devoid of air was established, and when, for fear of accident, I had even determined its absolute weight, I introduced in it the pulverised chlorate of potash, which I had heated in a current of pure and dry air to near its point of fusion. The neck of the globe having been cleaned to remove all traces of adhering chlorate, I plunged it into an oil-bath, heated to nearly 200°, and pumped the air out five or six times, passing into it each time pure and dry air, which had not been through the air-pump. After having brought the internal tension to exactly the same as it was at the first weighing, I brought it again into equilibrium by subtracting for this purpose weights from the pan to which the globe with the chlorate was attached. The globe being again filled with dry air, I unscrewed the stop-cock and filled the neck from its junction with the globe to within 10 centimètres of the cap fixed to its extremity with amianthus calcined with aqua regia. This amianthus I had transformed into a kind of felt, by stirring it up with water and then pouring the paste on to linen. Gases pass through this felt exactly as a liquid through a paper filter.

I then made a vacuum in the apparatus, heating the neck throughout nearly the whole of its length to carry off with the air the least traces of humidity which might have gained access during the introduction of the heated amianthus, and I determined the weight a third time, after having rarified the air to the same degree as in the two preceding weighings.

The apparatus being thus arranged, I placed the globe in a bath of magnesia, keeping its neck perfectly horizontal. To the stop-cock which terminated it, I adapted, by means of a caoutchouc connector, a hard, Bohemian glass tube, 60 centimètres long, by 1½ wide, drawn out at each end. The tube contained at each end a plug of felted amianthus, the remaining nine-tenths being filled with pure pulverulent silver precipitated by phosphorus. Before being placed in communication with the retort, it was carefully dried and weighed. This tube was followed by two others, curved U-shaped, filled with pumice-stone, moistened with sulphuric acid, likewise weighed; and finally, by a third U-tube, containing sulphuric pumice-stone, and intended to prevent the entrance of moist gas. The apparatus was terminated by a curved tube plunging to the depth of a millimètre only into water contained in a Woulf's bottle, which was furnished with a tube, curved, so as to allow of the connection with the disengaged oxygen.

As is well known, the decomposition of chlorate of potash demands excessive precautions to be effected

Numerical Order.	Apparent Weight of the Chlorate.	Weight of the Chlorate reduced to a vacuum.	Apparent Weight of the Evolved Oxygen.	Weight of the Oxygen reduced to a vacuum.	Weight of the Chlorine fixed by the Silver.	Weight of the Oxygen corresponding to the Chlorine fixed.	Corrected Weight of the Oxygen.	Oxygen evolved from 100'000 parts of Chlorate.	Chloride of Potassium produced from 100'000 parts of Chlorate.

experiments which I have made with the identical globes used in experiment No. I. and in experiments Nos. III., IV., and V.

No. I.

1. Weight of the globe of 1.729 litres capacity exhausted of air to 0.003 millimètres . . . 823.917
2. Weight of the globe after having been heated for six hours in a bath of magnesia to the point of rendering the lower part milky,—
 - a. After cooling for three hours . . . 823.913
 - b. After eight hours . . . 823.917
 - c. The next day . . . 823.9175

Nos. III., IV., and V.

1. Weight of the globe exhausted to 0.003 millimètres . . . 1736.409
2. Weight of the globe heated to redness in magnesia, after cooling for eight hours . . . 1736.410
3. Weight of the globe heated in magnesia from eight in the morning till four in the afternoon. The bottom was completely milky. Exhausted to 0.003 millimètres. After five hours' cooling . . . 1736.408
4. Weight of the globe the next day . . . 1736.409

I have employed for the analysis of chlorate of potash three specimens of the salt from different sources, but purified by the same process. One specimen served for experiment No. I., another for Nos. II. III., and a third for Nos. IV. and V.

(To be continued.)

On the Specific Gravity of Substances in the Liquid and Solid State, by O. RICHTER, Ph.D.

I beg leave to draw the attention of chemists to the singular fact, that, whereas in our handbooks and periodicals the various chemical and physical properties of substances are duly recorded, comparatively little is said about their specific gravity in the liquid and solid state. In most cases nothing at all is said about it, or we must content ourselves with a vague statement that the body is lighter or heavier than water, &c. Considering, however, that a correct and thorough knowledge of this property of matter is of paramount importance, both in a theoretical and in a practical point of view, I think that the simple mention of this fact will convince the chemical public of the necessity of at once setting to work in order to complete this portion of our science. Confining myself to the theoretical point of view, I shall observe, in the first place, that a knowledge of the atomic volume, which is obtained by dividing the atomic weight by the specific gravity, may lead to an insight into the nature and *modus operandi* of that mysterious cause which determines and modifies it. This volume is evidently the result of the combined repulsive energies proper to the various elements which are grouped together in the constituent molecule. Now, it is natural to suppose that every chemical element, in addition to its weight-equivalent, possesses also a volume-equivalent, with which it enters into combination, so that, supposing this latter to be as constant as the former, the atomic volume of chemical compounds would always be equal to the sum of the atomic volumes of their component elements. Experiment, however, teaches us that the cases which favour this hypothesis are comparatively of rare occurrence. Hence, in order to reconcile and explain the anomalies, we are obliged to suppose

a certain rate of increase or decrease in the atomic volume of one or more or all the constituents. The speculations of Kopp, Schroeder, Playfair, and others in this direction, made with the view of discovering the fundamental law of variation, to which the atomic volumes of all the elements are held to be subject, have as yet led to no satisfactory result. The inquiry was almost exclusively confined to inorganic chemistry; and here the number of ascertained cases was far too limited to arrive at valuable and extensive generalizations, while the organic part presented even more scanty material for the solution of this all-important problem.

The remarkable discoveries of Playfair relative to the atomic volume occupied by the acid and basic constituents of salts, and by these latter according as they are either anhydrous or associated with a larger or smaller amount of water of crystallisation, appear to conceal within them a profound philosophical truth, viz. that the eighth part of the volume of ice, which Playfair calls the unit volume, is really the standard whereby all the volume equivalents of the various chemical elements will one day be correctly measured and calculated. And here I may express the hope that this highly gifted philosopher, who is so intimately familiar with all the difficulties of this species of research, may still persevere in his efforts to penetrate the secret of the wonderful mechanism which controls and accomplishes all those endless variations in the atomic volume of chemical substances, and, what is very remarkable, which causes these variations to be superinduced upon the molecule without the slightest derangement taking place in the relative positions of its constituents. Hence, on the hypothesis that the chemical elements consist, not of single atoms, but of a definite number of such atoms associated according to some fixed principle of grouping, all the modifications in the physical properties of matter which we are in the habit of distinguishing by the terms allotropism, polymorphism, fusing and boiling points, crystalline form, optical and electro-magnetic polarity, &c., ought to be considered as so many functions of one and the same variable magnitude—namely, the atomic volume.

This view of the genetic relations between atomic volume and physical properties appears also to be fully borne out by experiment; for we invariably find that a change in the former involves generally a corresponding change in the latter, and *vice versa*; and, moreover, in thus modifying the physical conditions under which the chemical affinities are called into action, it is reasonable to expect likewise a corresponding change in the range and intensity of these latter. Accordingly, it is easy to see why sulphur and phosphorus, and, indeed, many other elements, if not the whole of them, if presented in one of their allotropic states, will be readily attacked by oxygen, while in another they remain passive towards that re-agent, at least up to a certain temperature.

I shall now, in the second place, take this opportunity in stating, that, for the last twelve years, I have devoted much time and labour in composing a catalogue of the densities and atomic volumes in the liquid and solid state of as many chemical substances as I could gather together from the various compendiums and journals within my reach. This catalogue contains, in round numbers, 600 inorganic and 350 organic substances, the sum of which amounts to what comes evidently to be a mere fraction in comparison with the hundreds of thousands of chemical productions, which, however carefully they may have been investigated in other respects, have yet been entirely neglected with regard to their densities in the liquid and solid state. The publication of

this catalogue, which, even in its present imperfect form, furnishes abundance of material for speculation, has only been delayed in the hope that chemists would soon make an united and vigorous effort in this direction.

With reference to this subject, I request the analysts to bear in mind that, when there exists a striking difference in the densities of a body as stated by different observers, it may in general be assumed that they have indeed examined one and the same substance, but which is the same in a chemical point of view only, and altogether different in a physical point of view. But even in such cases as the family of the sulphurs, or that of the oils of turpentine, where the differences in density are comparatively small, experiment clearly shows that, by varying their atomic volume, these substances have at the same time experienced certain changes in their physical properties, and which are sufficiently marked to individualise them as members of the same family. In the preceding remarks I have endeavoured to prove that chemistry has for its foundation not a simple, but a complex principle.

On the one hand, it is the purely chemical principle, whatever its nature may be, which determines the various forms of molecular arrangement, and it is the ponderable portion alone of the various kinds of atoms which in their constant weight-equivalents furnishes the basis of calculation. On the other hand, it is the purely physical principle, whatever its nature may be, which determines the atomic volume of the molecules, and it is the imponderable portion alone of the various kinds of atoms which in their variable volume-equivalents furnish the basis of calculation.

Accordingly, our tree of chemical knowledge splits up into two main branches, for which I would propose the terms Pondo-Chemistry and Impondo-Chemistry. If this division be correct, it follows that, in order to unravel the mixed and complex character of the phenomena, our present methods of analysis, however well adapted they may be for that branch which is engrafted upon the chemical principle, will require to be modified so as to become available for the other branch also.

CORRESPONDENCE.

Chemical Nomenclature.

To the Editor of the CHEMICAL NEWS.

SIR,—As special attention has lately been drawn to the subject of Chemical Nomenclature, perhaps a few additional remarks thereupon might not be out of place in your valuable journal.

I think it is sufficiently obvious that many of those who have offered us a new terminology expect more from words than they are lawfully capable of expressing. It is too much to suppose that a single word shall denote the constitution of a body, the number of atoms it contains of certain elements, and the names of the elements themselves. Your correspondent "Inquirer" (in No. 106) appears to have perceived this; and humorously asks of one propounder by what name Albumen is recognised in his system. I, for my part, am considerably at a loss to see what is to be gained by the employment of this "concentrated essence" of language; and it would be more difficult, perhaps, for the memory to retain the all-comprehensive name than the facts and theories vainly sought to be included under it.

The purely arithmetical systems hitherto proposed abound, to excess, with the most unmusical and distasteful names,—names which will never be adopted as components of a great and useful arrangement, any more than,

to take a well-known instance, the Latin verses constructed from tables can be combined to a poem. From such systems, too, the Natural History element is too much excluded; so that it would be hardly an unwarrantable presumption to anticipate for them the fate which, in Botany, has attended the classification of Linnaeus.

So extensive a scheme of innovation as must be necessarily contemplated by any one who wishes to revolutionize an extensive nomenclature is one only suited for veteran practitioners. And, even from them, how slowly have alterations been adopted! The well-matured and excellent views of Gerhardt have been a considerable number of years meeting with their present success, and that is by no means complete. What, then, shall be said of some claims which have been recently advanced?

On the whole, therefore, I would venture to recommend that the steps which are taken to alter our nomenclature should be as gradual as possible, inasmuch as small changes are always discussed more soundly and adopted with greater security. This proceeding would also be incalculably more just to inventors, whose proposals could thus be examined with brevity and ease.

I have submitted these remarks in the hope, on the one hand, of moderating over-hasty theoretical zeal, and, on the other, of perhaps furnishing one or two tests for the stability of proffered systems. Without adopting some such considerations as these, we shall have our terminology laid open to the just though unwelcome charge, "Tot chemici, tot theoriæ."—I am, &c.

EDMUND J. MILLS.

Analysis of Yeast.

To the Editor of the CHEMICAL NEWS.

SIR,—In reference to your correspondent's (Mr. D. Clifton) enquiry about analysis of yeast, allow me to communicate briefly the following:—There are analyses of brewer's yeast quoted in Schubarth's well-known work, *Handbuch der technischen Chemie und Chemischen Technologie*, Vol. iii. Berlin: 1851. On page 506 we read. According to Schlossberger and Wagner, brewer's yeast, deduction being made of the ashes, is composed as follows:—

	Schlossberger.		Wagner.	
	Oberhefe. ¹	Unterhefe. ²	Oberhefe.	Unterhefe.
Carbon	50.05	48.03	44.372	49.761
Hydrogen	6.52	6.25	6.040	6.804
Nitrogen	11.84	9.80	9.203	9.171
Oxygen	31.59	35.92	40.385	34.264

Beside this a most elaborate paper has been published in 1845, by Professor G. J. Mulder, at Utrecht in his *Scheikundige Onderzoekingen*, Vol. ii., pp. 409 to 482, this paper contains, Mulder's researches on the so-called German dried yeast, in reality a product obtained in very large quantities from the distilleries at Schiedam, Holland; that yeast is composed of a cellular tissue $C_{12}H_{10}O_{10}$, and of a proteine compound $15(C_{40}H_{22}N_{10}O_{12}) + 8S$. The ash in the anhydrous dried yeast amounts to 10 per cent. and contains phosphoric acid, phosphate of lime, and other saline matter usually met with in substances of vegetable origin. The cellular tissue amounts to from 30 to 45 per cent. and the proteine compound from 55 to 70 per cent. Yeast contains moreover a very small amount of margaric and elaic acids. In Mulder's works on Wine, and that on Beer, valuable information is given about fermentation and yeast. I could quote several other sources which will give information on this subject, but think this may satisfy your correspondent.

I am, &c.

DR. A. ADRIANI, F.R.N.I.E., &c.

Laboratory, Edinburgh, December 23.

¹ Yeast from upper, or surface fermentation.

² Yeast from under fermentation.

On Butter and Other Fats.

To the Editor of the CHEMICAL NEWS.

SIR,—When I first put forward my original paper, as well as the subsequent ones, on Butter, I felt so convinced of the accuracy of my statements that I had no idea they would have elicited so much discussion.

In his conclusion No. 1, Dr. Ballard has set out with an erroneous quantity, and would appear to make out that butter is not entirely soluble in ether at 65°. Of course, if a person uses an immoderate quantity, which I contend he has, what otherwise could be expected?

Since reading Dr. Ballard's last paper, I have made the following experiments, which go far to make good all I have previously asserted:—

Experiment 1.—Ten grains of pure butter, on being dissolved in one drachm of ether, by agitation of the phial in the warm hand for a minute or so, and kept at a temperature of 65° for twelve or more hours, remained permanent; indeed, that which I made two months ago, when I first wrote my paper, has scarcely deposited, and that little is due to cold.

Experiment 2.—Twenty grains, similarly treated, dissolved at first, but did not continue permanent longer than an hour or so, owing to an insufficiency of ether.

Experiment 3.—Ten grains each of butter and beef dripping, dissolved in one drachm of ether, and the bottle held in the hand for a minute or so, the beef fat, from being softer than the butter, dissolved soonest; but when both were dissolved and kept at a temperature of 65° the beef fat deposited to a certain extent, and at 55° the deposit of beef fat occupied full half the bottle. By this we can readily detect beef fat in butter, the deposit being scalliform to the eye, but is in reality a mass of margaric crystals, and which did not re-dissolve in a room heated to 65°.

Experiment 4.—Twenty grains of beef fat, similarly treated, deposited considerably on standing, and at 55° to more than half the bottle full.

Experiment 5.—Ten grains each of butter and lard, similarly treated, although held in the hand for a long time, could not well be dissolved, but remained suspended just like a soap of hartshorn and oil, occupying full four-fifths of the bottle at 65°.

Experiment 6.—Ten grains of mutton dripping, similarly treated, at 65°, with one drachm of ether, deposited to the extent of three-fourths of the bottle full.

Hence, we come to the practical conclusion that the stearin of both lard and mutton dripping is nearly, if not quite, insoluble in ether at 65°, which establishes the point I originally founded my paper upon, and that Dr. Ballard, who evidently means well, is greatly mistaken in supposing that butter renders lard more soluble, according to his conclusion No. 7, as proved by my experiment No. 5.

The above simple set of miniature experiments shows unmistakably, notwithstanding all that has been advanced against it, that the ether test is preeminently worthy of confidence in every respect; in short, combined with the microscopic method I have since published, comprises all that is required in the investigation of fatty bodies generally.—I am, &c.

JOHN HORSLEY, F.C.S.

County Analyst's Laboratory, Police Station, Cheltenham.

MISCELLANEOUS.

The approaching Eclipse of the Sun.—At the last meeting of the Manchester Literary and Philosophical Society, Mr. Dickinson read a "Note on the Eclipse of the Sun, December 31, 1861." This eclipse, being small compared with several that have lately occurred,

will not attract so large an amount of general attention; it will, however, be of considerable interest to scientific persons, and in the hope that the members of this Society will not consider it an unimportant phenomenon, the following results are submitted to enable them to compare their observations with the computed times. Calculations for Manchester (Royal Infirmary), lat. N. 53° 29', long. W. 2° 14'.

	H.	M.	S.
Eclipse begins, December 31	1	49	19
Greatest Phase	2	49	9
Eclipse ends	3	45	29

mean time at Greenwich. Magnitude of the Eclipse (Sun's diameter = 1) 0.413 on the Sun's southern limb. Angle from North Pole, of first contact, 143° towards the West; last contact, 108° towards the East. Angle from vertex, of first contact, 157° towards the West; last contact, 80° towards the East, for direct image.

Long Tube Barometer.—After a recent meeting of the Institute of Civil Engineers, Mr. R. Howson exhibited in the library a Barometer, consisting of a long tube freely suspended open end downwards, a cistern which was of a tubular shape, and a "stalk." The stalk was a glass tube, sealed at both ends, attached firmly at its lower end to the bottom of the cistern, and rising axially up the tube until it nearly reached the surface of the mercurial column. The consequence of this arrangement was, that the top of the stalk came into the region of very low pressure, and there was an excess of pressure tending to force the cistern upwards. This excess was represented by the weight of the cistern (and stalk), and the contained mercury, so that under a given atmospheric pressure, the cistern would always hang suspended at a given level. When the pressure of the atmosphere rose, a portion of mercury left the cistern and passed into the tube, and the cistern alone arose, until the level was replaced by the immersion of the glass which formed the tube. When the pressure fell, the converse took place, an elongated scale was thus produced, the extent of range being dependent upon the relative areas of the tube, and of the glass which composed it. The action might also be simply viewed as that of a long piston, or plunger, with a liquid packing, having a vacuum on its upper side, and a self-graduating weight attached to its lower side.—*Mechanics' Magazine.*

ANSWERS TO CORRESPONDENTS.

* * In publishing letters from our Correspondents we do not thereby adopt the views of the writers. Our intention to give both sides of a question will frequently oblige us to publish opinions with which we do not agree.

Magenta.—The correct way is by distillation. Different naphthas may be compared by ascertaining what per-centage comes over below 212°. The more the better. Benzine and benzol are the same thing. The quality of nitrobenzol can be readily ascertained by the smell, it should be very delicate and pure, and should leave no unpleasant odour when a drop is evaporated on the hand.

G. H. F.—Your question is exceedingly elementary. Sulphide of calcium is composed of one equivalent of sulphur and one of calcium, the metallic basis of lime. Sulphate of lime, on the contrary, consists of one equivalent of lime and one equivalent of sulphuric acid. The former has the formula CaS, and the latter, CaO.SO₃. They are totally distinct bodies, and have no resemblance to each other in their properties.

J. Shields.—A letter addressed to M. Kopp, at the Chemical Society of Paris, would find him.

- Acids, malic and peptic**, transformation of cane sugar into, 291
- Acid, perchloric**, and its hydrates, 165
perchromic, 69
permanganic, composition and properties of, 103
phenic, for disinfecting purposes, 60
phosphoric, explosion in making, 83
preparation of pure, 13
separation of, from sesquioxide of iron and alumina, 75
picramic, 193
piperic and hydropiperic, 315
propionic, transformed into lactic, 290
pyroigneous, 156
rosalic, and rosolates, 90
sulphuric, 12, 156
with acetic acid, 333
monohydrate of, 26
pure, 40
sulphurous, new test for, 83
tartaric, 176
with acetic acid, 333
tartalic, and thorina, obtained in crystals, 103
titanic, detection of, 84
veratric, 70
- Acids, compounds of two**, 333
of phosphorus, 253
- Addimetric process**, 195
- Aconitine**, medicinal, 60
- Acoustics**, Professor Helmholtz on, 165
- Adriani, A.** on white lead, 43
on analysis of yeast, 338
- Adulteration of butter**, 230, 233, 306, 309, 320, 292, 332, 339
of food, 226
of white lead, 69
- Air**, atmospheric, normal variabilities of the properties of, 43
- Alochemy**, 136
in the nineteenth century, 261
- Alcohol**, arseniuretted, for the preservation of objects of natural history, especially insects, 274
- Alcohol in wines**, estimation of, 208, 220, 252, 263
- Alcoholic spirits**, copper, lead, and tin in, 117
- Aldehyde**, compound of, with oxide of ethylene, 334
modifications of, 226
- Alkali manufacture**, 172
- Alkaline and earthy cyanides**, 213
- Alkaloid and other constituents of coca leaves**, 47
- Alkaloids**, diagnosis of the, 2, 113
of the quinquinas, estimation of the, 327
- Alloys, metallic**, 68
of copper and zinc, 91
of lead and tin, 316
of titanium and iron, patent for, 11
- Alum**, 156
in bread and flour, 326
- Alumina**, separation of phosphoric acid from, 75
- Aluminium bronze**, 58
- Silicofluoride of**, 255
working in, 79
- Aluminous mineral**, vanadium in an, 241
- Amalgamating and effecting the separation of gold from earthy and other matters containing the same**, 69
- American Journal of Science**, 334
- Oil springs**, 152
- Ammonia**, action of, on chlorides, 136
compounds of, with salts of copper and cobalt, 290
fixation of, 150
phospho-molybdate of, 75
and its salts, influence of on precipitation of certain metals, 150
specific gravity of, 150
- Amser, E.** protochloride of iron, 75
- Analysis, spectrum**, 302, 328
liquid diffusion applied to, 86
of mineral waters, and on the arrangement of the results, 29
of yeast, 338
- Analytical notes**, 75
by H. Rose, 218
- Andrews, Dr.** on the effect of great pressures combined with cold on the six non-condensable gases, 158
- Animal substances**, preserving, patent for, 123
or vegetable matters, preserving, 267
and vegetable, relation of, to the inorganic kingdom, 33
- Aniline blue**, 262
colours, 156, 196, 209, 220
estimating the value of, 320
properties of the sulphate of, 286
- Answers to Correspondents**, 14, 28, 42, 56, 70, 84, 98, 112, 124, 136, 162, 164, 176, 188, 214, 226, 240, 254, 268, 280, 292, 306, 320, 334, 339
- Antichlores**, patent for, 11
- Antimony in copper**, 264
selenide of, 116
separation of gold and platinum from, 284
- Appelbaum, M.** solder for brass instruments, 235
- Aroma and other properties of coffee and cocoa**, preserving the, from the effects of the atmosphere, 267
- Arseniate of soda**, 156
- Arsenic in copper**, 264
eating in Styria, 19
estimation of, 75
selenide of, 116
- Arsenical paper-collars**, 214
poisoning, 292
and sulphurous fumes, suppression of, emitted during the first operation or calcination of copper ores, 200
- Arsenious acid**, mineralisation of, 262
- Arseniuretted alcohol** for the preservation of objects of natural history, especially insects, 274
- Artificial leather**, 174
manure from Newfoundland, 14
stone and cement, 185
- Aschoff, H.** composition and properties of permanganic acid, 103
perchromic acid, 69
- Ashworth, H.** on bleaching, 169
- Asphodel**, commercial products of the, 56
- Asamar**, preparation of, 27
- Assay of silver by the moist way**, 99, 125, 137, 204, 231, 297, 321
- Atmosphere**, impregnating the, with perfuming or purifying vapours, 201
nitrous and nitric acids in the, 136
oxygen compounds of nitrogen in the, 285
variability of the properties of, 43
- Atmospheric lines of the solar spectrum**, and on certain spectra of gases, 140
ozone, 166
- Atomic weights**, Stas on the relations existing between, 124, 181, 206, 215, 228, 248, 257, 270, 282, 297, 307, 324
- Aureolin**, 268
- Bailey, W.** coating metals and metallic alloys, 68
- Baker, W.** on white lead, 74
- Ballard, Dr. E.** on the adulteration of butter, 233, 320, 322
- Bannehr, J.** improvements in the manufacture of manure when urine is used, 162
- Bark**, chemical products from, 288
- Barometer**, oscillations of the, 211, 235
long tube, 331
water, at the Crystal Palace, 150
- Barre, E. H.** manufacture of paper from a pulp obtained from wood, 215
- Bartlett Brothers and Co.** on the induration and preservation of stone, 247
- Baryta**, hydrate of, 124
sulphate of, 156
- Bases**, ethyl, exact separation of the, 71
production of the, 88
Bath for high temperatures, 319
- Baudrimont, M. E.** on the action of perchloride of phosphorus on several elements, 335
- Bauxite**, 241
- Baxendell, Mr.** observations of comet 1, 1861, 210
- Bechamp, A.** researches on the separation, by the wet way, of gold or platinum from tin and antimony, reduction of perchloride of iron by platinum, 264
- Bequerel, M.** on electro-chemical colouring and the deposition of peroxide of iron on plates of steel and iron, 6
- Beilstein, salgemine**, 41
- Bernier, J. E.** artificial leather, 174
- Bessemer process of making steel**, 112
- Bichromate of potash**, 156
- Binitronaphthalin**, 28
- Binks, C.** manufacturing certain gases applicable in generating heat and light, and in bleaching, 40
- Binney, E. W.** on the Permian beds of South Lancashire, 339
- Binoxide of hydrogen**, preparation of an ethereal solution of, 57
- Bismuth in copper**, 264
iodide of, double salts of, 225
oxychloride of, 83
selenide of, 116
- Blauiphide of carbon in gas**, 24, 38, 62
- Bituminous substances**, distillation of, 251
- Black varnish for zinc**, 19
- Bleaching**, 123, 169
powder, 156
wood, 253
- Blockey, J. S.** economising the waste from vitriol chambers, 278
printing Prussian blue, 163
- Blomstrand, C. W.** bromine compounds of molybdenum, 187
the chlorides and bromides of tungsten, 163
- Blondel, C. M. J.** manufacture of paper from a pulp obtained from wood, 213
- Blood**, products of putrefaction of, 263
stains, analysis of, 248
- Blue**, aniline, 262
colour from cotton-seed oil, 291
- Boedeker, C.** new test for sulphurous acid, 83
- Boiling points of liquids**, 14, 20
- Boinet, Dr.** on the preparation of a natural iodine wine, 302
- Bolley, Professor**, on the dangers arising from feeding steam boilers with certain waters, 316
on the physical properties of alloys of lead and tin, 316
- Booth, W. R.** phosphate of sesquioxide of iron, 175
- Boracic acid in sea-water**, 16
- Borate of lime and soda**, 182
- Böttger, Professor R.** on the preparation of an ethereal solution of binoxide of hydrogen, 57
on a black varnish for zinc, 19
permanent source of ozone, 69
permanganate of potash, 69
- Bouet** on spontaneous decomposition of gun-cotton, 200
- Boutlerow, M.** synthetic formation of a saccharine substance, 253

 Griffin, J. J. description of a gas furnace for general chemical use, 233
 Grocers v. Doctors, 188
 Guanos, Patagonian, 290
 Guignet, M. another chrome green, 253
 Gums, artificial, 156
 Gun water, 240
 Gun Barrels, browning for, 320
 Gun cotton, 41
 spontaneous decomposition of, 290
 Gunpowder, products from the combustion of, under different pressures, 18
 Gunpowder, white, 13, 105, 128, 149
 Guy, W. A. on the colour tests for strychnia and the diagnosis of the alkaloids, 2, 114
 Gyroscope, 199
 HAINES, R. on the analysis of mineral waters, and on the arrangement of the results, 29
 notes on nitrification, 245, 259
 on the presence of nitrates in mineral waters, and on the production of saltpetre, 153, 165, 194
 Harris P. pure sulphuric acid, 40
 Hauer M. artificial chalybeate water, 69
 Hay, W. J. glue or composition suitable for covering or caulking of ships, &c. 251
 Hair wash, 268
 Hall, V. obtaining colouring matters, 135
 Hallett, G. pigments for coating surfaces, 83
 Hamilton, J. fixing colouring matters, 306
 Hancock, C. L. an improved fuel, 26
 Harcourt, Mr. on the action of certain gases on the peroxides of potassium and sodium, 264
 Hayes, Dr. A. A. on the occurrences of soluble compounds of copper, lead, and tin in newly distilled alcoholic spirits, 117
 Hebeon, D. obtaining fresh water from salt water, 288
 Helmholtz, H. L. F. a course of two lectures on musical acoustics, and on the physiological and psychological causes of musical harmony and discord, 105
 Henry, M. improvements in distilling and rectifying, and in apparatus employed therein, 251
 Heraclitus, W. nitrates in water, 253
 Hermann, R. on didymium, lanthanum, cerite, and lanthanocerte, 72, 87
 Herring pickle, 37
 Heydenreich, E. on phosphate of sesquioxide of iron, 158
 Hirsch, W. insulating the conducting wires used for telegraphic purposes, 68
 Hofmann, Dr. decomposition of cyanurate of ethyl, 32
 on the importance of the study of chemistry, 7, 34
 Holland, G. improvements in the mode of, and apparatus used in the process of fermentation, 267
 Honey, obtaining an article resembling, 26
 Hooker, Sir W. J. commercial products of the asphodel, 66
 Horsley, J. on the estimation of alcohol in wine, 208, 252
 on the adulteration of butter, 230, 306, 309, 332, 339
 on alum in bread and flour, 326
 on the chemico-microscopical characters of fatty matters, 309, 332
 on the copper test for sugar, 286, 290
 specific gravity and solid contents, 288
 Houzeau, M. normal variability of the properties of atmospheric air, 43
 Hudson, F. white gunpowder, 105, 149
 Hunt, T. S. on osone, nitrous acid, and nitrogen, 193
 Hydrocarbons, patent for obtaining solid and liquid from coal, peat, &c. 68
 Hydrogen, action of, on nitrobenzene, 70
 binoxide of, preparation of an ethereal solution of, 67
 phosphuretted, 151
 introduction of, into organic compounds, 164
 Hydrogen and oxygen, ozonised, 74
 Hydrogen, peroxide of, 214
 Hydroperiperic acid, 815
 Hypochloric acid as an oxidiser and solvent, 57
 Hypophosphite of lime, 312
 Hyposulphite of soda, 156
 Hyposulphites, double, 111
 Ice and snow, relative bulks of, 268
 Incrustation in steam-boilers, and in tanks for containing the feed for the same, preventing, 186
 India-rubber, hard, 231
 vulcanised, 97
 Induction coil, on the application of the, to spectrum analysis, 118, 130
 nature of the spark of Ruhmkorff's, 7, 21
 Induration and preservation of stone, 247
 Insulating the conducting wires used for telegraphic purposes, 68
 Inorganic chemistry, Frankland's lectures on, 51, 65, 93
 Inorganic kingdom, relation of the animal and vegetable kingdom to the, 38
 Iodic acid, behaviour of sulphurous to, 83
 Iodide of bismuth, double salts of, 225
 Iodide of cadmium, 334
 Iodidi, liquor ferri, 117
 Iodine, 134
 quadra-chloride of, 187
 wine, a natural, 362
 in tinctures, estimation of, 70
 Iron, 276
 in clay, 257
 dissolved in dilute acids, oleaginous matter formed, 4
 electro-chemical colouring of, 5
 influence of ammonia and its salts on the precipitation of, 150
 manufacture of, 91, 103
 ore, Canadian, 292
 Spanish, 164
 oxalate of, 809
 oxide, preparation and application of hydrated, 331
 phosphate of sesquioxide of, 158, 175
 protochloride of, 75
 protosulphate of, 156
 reduction of perchloride of by platinum, 284
 sesquioxide of, separation of phosphoric acid from, 75
 sheet, patent for, 39
 silicon in, 75
 and steel, 110
 Iron, steel, and cast steel, patent for, 11
 and titanium, patent for alloys of, 11
 varnish for, 56
 JACOB, J. apparatus for obtaining gas, 267
 JACOBSEN, M. on formic acid and the hemihedrisation of formiate of strontia, 310
 Jaloureaux, A. F. protecting and insulating subterranean telegraph wires, 26
 Janssen, A. researches on hypophosphite of lime, 312
 Jenkin, F. on thermo-electric currents in circuits of one metal, 222
 Jerrall, J. preparation of fish and marine animals for manure, 316
 Jennings, J. G. capsules or covers for the necks of bottles and jars, 174
 Jones, Dr. H. Benoe, on the occurrence of phosphate of lime in the human urine, 287
 Jones, E. T. the suppression of arsenical and sulphurous fumes emitted during the first operation or calcination of copper ores, 200
 Johnson, G. J. on the adulteration of white lead, 69
 J. H. the application of certain vegetable substances to the manufacture of paper pulp, 224
 tanning hides and skins, 184

- Jolly, M. specific gravity of ammonia, 150
Joubert, F. glass, 42
Jouvin, M. destructive action of minium on the hulls of iron ships, 44
preparation of rosolic acid and of rosolates, 90
Jullion, J. L. apparatus used in the manufacture of paper, 288
treatment of soda waste and sulphurets, 174
Jumel, new compound by the action of hydrogen on nitrobenzene, 70
KARSTEN, Dr. H. behaviour of sulphurous to iodic acid, 63
nitro-iodic acid, 111
quadrachloride of iodine, 187
Kaolin, feldspar, and clay, analyses of, 255
Kerosene, 189, 300
Kirschhoff and Bunsen, rubidium and cesium, 44
Knopp, W. estimation of carbon in organic substances, 18
Kolbe, M. introduction of hydrogen into organic compounds, 164
Kopp, M. E. on the artificial colouring matters derived from aniline, 208, 220
certain copper and zinc alloys, 91
on cinnamates and nitrocinnamates, 334
Kottula, C. N. soap, 316
Kraut, Dr. diamylphosphoric acid, 226
double hyposulphites, 111
Kuhlman, M. blue colour [from cotton seed oil, 291
LANCASHIRE, chemical manufactures of South, 156
Lactic, propionic acid transformed into, 290
Laird, improvements in the treatment of certain ores containing metals, and in obtaining products therefrom, 251
Landerer, M. reaction of strychnia, 76
scapolites of Mylos, 254
Lange, T. manufacture of sub-oxy-sulphate of lead, 174
Lanthano-cerite and cerite, 72, 87
Lanthanum, didymium, cerite, and lanthano-cerite, 72, 87
Lard and butter, chemico-microscopical characteristics of, 309
Lark, J. Portland cement, 185
Lasserre, A. G. manufacture of fuel, 184
Laurence, J. E. some observations on the sensibility of the eye to colour, 49
Laurens, M. on a new method for the production of chlorine, 246
Lauth, Ch. on aniline blue, 262
Lava and other volcanic substances for employment in certain arts and manufactures, patent for, 192
Lea, C. on the effects of reducing agents upon nitrate of ethyl, 280
on the estimation of nitrogen, and on an acidimetric process, 195
on the exact separation of the ethyl bases, 71
on the formation of picramic acid, 193
on the preparation of nitrate and nitrite of ethyl, 219
on the preparation of urea from ferrocyanide of potassium, 269
on the production of the ethyl bases, 83
Lead, action of water on, 172
aqueduct pipes, local decomposition in, 189
copper, and tin in alcoholic spirits, 117
manufacture of white and salts of, 288
separation of, from mercury, 218
sub-oxy-sulphate of, 174
and tin, alloys of, 316
Lead, white, 43, 74
white, adulteration of, 69
Leather, artificial, 174
coating for, 82
tanning, 288
Leblaug, M. new oxychloride of bismuth, 83
Leclerc, M. fresh paint in apartments, 84
Lectures, taking notes of, 320
Leeds, water at, 239
Leidemann, A. the manufacture of sub-oxy-sulphate of lead, 174
Lemaire, M. J. on the use of phenic acid for disinfecting purposes, and its mode of action, 60
Lennox, A. W. on bromide of carbon, 21
Lenses, grinding, 226
Lennsen, M. estimation of arsenic, 75
Leoroy, C. N. improved grease for lubricating the frictional surfaces of machinery, 98
Lepidoptera, scales of some diurnal, 331
Leprieur, M. on the employment of arseniuretted alcohol for the preservation of objects of natural history, especially insects, 274
Leslie, J. manufacture of gas, 81
Lotheby, H. report on the sanitary condition of the City of London for the quarter ending June 22, 1861, with table of the composition of the river, and the water from City pumps, 76
the City pumps, 260
Leuchs, ether formed by fermentation, 111
influence of sulphur on fermentation, 111
Leucic acid, 287
Levoir, L. C. on the best form for chimneys, 60
on cracking glass, 84
urine of omnivora, 112
vulcanised Indian-rubber, 97
Lieben, M. constitution of the acids of phosphorus, 253
modifications of aldehyde, 226
Light, deleterious effect of, on potatoes, 327
Lightfoot, J. test for the purity of acetic acid, 290
Lights and lighthouses: Report of the Commissioners appointed to inquire into the condition and management of lights, buoys, and beacons, 37, 133
Lime, hypophosphite of, 312, light at the South Foreland, 279
phosphate of, in urine, 287
and soda, borate of, 182
superphosphate of, 156
Lindau, M. double salts formed by iodide of bismuth, 224
Liquid diffusion applied to analysis, 86
Liquor Ferri Iodidi, 117
Lithia, influence of, on fructification, 19
Lithium spectrum, blue band of the, 303
Loir, A. and Ch. Drion, on the solidification of carbonic acid, 18
London, water supply of, 176
Longmaid, W. iron and steel, 110
Long-tube barometer, 339
Lorberg, W. obtaining and utilizing the chemical products of spent bark commonly called tan, 288
salts of manganese, 69
Lubricating frictional surfaces, grease for, 98, 122
Luca, S. de, on the formation of oil in olives, 334
Ludolt, adulteration of wax with paraffine, 83
Lunar phenomenon, 239
Luteoline, 150
MACHUCA, M. transformation of propionic into lactic acid, 290
McLeod, H. chemical nomenclature, 317
Magenta, dyeing, 55
Magnetic chrome oxide, 111
Maclech, J. M. on the active principle of cornus Florida, 198
on the chemical constituents of coca leaves, 313
on the detection of croton oils in mixtures, 32
Malaguti, M. Patagonian guanoe, 290
Malle and pectic acids, transformation of cane sugar into, 291
Mallet, J. W. note on the extent to which mercury volatilises along with the vapour of water at 100° C., 102
Malt liquors, refining, 175
Maltby, W. manufacturing a glutinous or viscous substance to be used in dressing textile fabrics, and for other such like processes, or in brewing and distilling, 175
Manchester Literary and Philosophical Society, 210, 236, 262, 276, 330
Manganese, influence of ammonia and its salts on the precipitation of, 159
salts of, 69
"Manual of Chemistry, Descriptive and Theoretical," (Part I.) review of Dr. Odling's, 174, 250, 304
Manual of Qualitative Analysis, by Galloway, 211
Manufactures, chemical, of South Lancashire, 156
Manure, 162, 214
preparation of fish and marine animals, for, 316
Manures, estimation of nitrogen in, 238
Marchand and Girardin, herring pickle, 27
Marking ink, permanent, 56
Martin, J. preparation of red dyes, 224
Match and phosphorus manufacture, on the origin and progress of the, 16, 31, 45, 77, 89
Matches, phosphorus, 69
Mayer, F. F. on the weighing of moist precipitates, 16
Mayer, W. separation of phosphoric acid from sesquioxide of iron and alumina, 75
Medicine, Retrospect of, 185
Medicinal extracts, 275
Medlock, H. brewing malt liquors, 122
Menard, A. F. tanning leather, 288
Mirck, W. veratric acid, 70
Mercury, estimation of, 218
extent to which it volatilises along with the vapour of water, 102
fluorine, and silicon, salts of, 225
selenide of, 116
separation of from silver, 218
from lead, 218
Metals and metallic alloys, 68
Müller, Dr. on spectrum analysis, 159
Miller, J. S. and T. P. fixing colouring matters, 277
Mills, E. J. sparteine, 287, 306
on Chemical Nomenclature, 338
Mincher, W. coating metals and metallic alloys, 68
Mineral waters, analyses of, 29
nitrates in, 153, 165, 194
in Siam, 28
Minimum thermometer, Casella's, 235
Minium, action of on the hulls of iron ships, 44
Moffatt, Dr. F. on atmospheric ozone, 166
Mohr, Dr. F. a solution of starch for volumetric analysis, 166
Moist precipitates, weighing of, 15
Molybdenum, bromine compounds of, 187
selenide of, 116
Monohydrate of sulphuric acid, 26
Mordanting and the manufacture of products to be used in mordants and otherwise, patent for, 185
Morren, M. on spectrum analysis, 302
Morris, D. A. sheet iron, 32
Moyle, H. J. minerals in Siam, 28
Mulder, G. J. chemical researches on the assay of silver by the moist way, 89, 125, 137, 204, 231, 297, 331
Müller, M. preparation of hydrate of baryta, 124
Mushet, R. manufacture of alloys of titanium and iron, 11
manufacture of cast steel, 110, 224
improvements in the manufacture of iron and steel, and of cast steel, 11
Mylos, soap-stone of, 254
NAPHTHALINE colours, 197, 304
Neustadt, J. manufacture of pure phosphoric acid, 13
New system of chemical nomenclature, 281, 317
Newfoundland, artificial manure from, 14
Newlands, J. A. R. suggestions for a new system of chemical nomenclature, with reference more particularly to organic substances, 281, 332
Newton, W. E. cementation, 266
Nichols, J. R. local decomposition in lead aqueduct pipes, 139
Nickel, influence of ammonia and its salts on the precipitation of, 150
Niemann, Dr. A. on the alkaloid and other constituents of coca-leaves, 47
Nitrate of ethyl, effects of reducing agents upon, 230
and nitrite of ethyl, preparation of, 219
of silver, preparation of, 98
of soda, 98
Nitrates in water, 153, 165, 194, 239, 253
Nitric, storing, 40
Nitric Acid, *see* Acid, Nitric
Nitrication, 245, 259
Nitrobenzene, action of hydrogen on, 70
Nitro-cinnamates, 334
Nitrogen, estimation of, and on an acidimetric process, 195
in manures and other substances, 238
Nitrogen, nitrous acid, and ozone, 193
Nitro-iodic acid, 111
Nitro-prusside of sodium, 152
Nitrous acid, ozone, and nitrogen, 193
and nitric acid in the atmosphere, 136
Nobert's test plate and the striae of diamons, 128
Nomenclature, chemical, 281, 317, 332, 338
scientific, 254, 279
Non-conducting substances, preparation for the deposition thereon of metals by electric action, 110
Nordenakjoeld, A. E. obtaining thorina and tantic acid in crystals, 102
Norton, F. O. pure sulphuric acid, 40
Notation and equivalents, Gerhardt's, 85
ODLING, Dr. "A Manual of Chemistry, Descriptive and Theoretical," review of, 174, 250, 301
Oil of cajuput, 124
croton, in mixtures, detection of, 32
formation of in olives, 334
regions of Canada, 201
springs in America, 152
wells of Pennsylvania, 164
Oils, coal, petroleum, and other distilled, 54
and varnishes, purifying, 26

- Ointment for the cure of sores, 251
Ointments, glycerine, 6
Oleaginous matter formed on dissolving different kinds of iron in dilute acids, 4
Olives, formation of oil in, 334
Optum, caffeine as an antidote to the poisonous effects of, 47
Oppenheim, Dr. on the camphor of peppermint, 315
Ores containing metals, obtaining products therefrom, 251
Organic substances, estimation of carbon in, 13
 estimation of oxygen in, 97
 patent for preserving, 69
Osann, M. H. on ozonised hydrogen and oxygen, 74
Oxacanthine, 41
Oxalate of iron, 309
Oxalic acid, anhydrous, 75
Oxide of chromium, magnetic, 111
Oxychloride of bismuth, 83
Oxygen, compounds of nitrogen in atmospheric air, 285
 estimation of in organic matters, 27
 and hydrogen, ozonised, 74
Oysters, phosphorus in, 268
Ozone, atmospheric, 166
 arous acid, and nitrogen, 193
 permanent source of, 69
Ozonised hydrogen and oxygen, 74
Paint, fresh, healthfulness of, 84
Paper collars, arsenical, 214
Paper, manufacture of, 288
 from Indian corn, patent for, 55
 patent for, 11
 pulp, manufacture of, 224
 patent for, 123
 from wood, 213
Paraf, M. on luteoline, 160
Paraffin, adulteration of wax with, 83
Paraguay tea, amount of theine in, 111
Parrish, E. on kerosene, 300
Paste from wood, to be used in the manufacture of various articles, patent for, 134
Pasteur, M. spontaneous generation, 292
Patagonian Guano, 290
Patents, grants of provisional protection for six months, 110, 123, 135, 163, 175, 186, 201, 214, 225, 238, 252, 267, 278, 289, 305, 317
 inventions protected for six months by the deposit of complete specifications, 110, 267, 278
 notices to proceed, 111, 123, 163, 175, 186, 201, 214, 225, 238, 267, 278, 289, 305, 317
Pattison, R. C. and A. M. method of fixing colours in connection with the printing of woven fabrics and yarns, 277
Pauli, Dr. F. on the production of graphite by the decomposition of cyanogen compounds, 78
Pebl, M. combustible gas in a salt mine, 188
Pectic and malic acids, transformation of cane sugar into, 391
Peck, A. treating or preparing textile materials and fabrics, 277
Pelouze, amount of sulphur existing in pyrites, 276
Pennsylvania, oil wells of, 164
Pepper, J. H. sulphuric acid, 12
Peppermint, camphor of, 315
Perchloric acid and its hydrates, 155
Perchloride of phosphorus, action of, on some elements, 338
Perchromic acid, 69
Permanganate of potash, preparation of, 69
Permanganic acid, composition and properties of, 103
Permian beds of South Lancashire, 230
Peroxide of hydrogen, 214
 of iron, deposition of, on plates of steel and iron, 5
Peroxide of potassium and sodium, action of gases on, 264

 on perchloric acid and its hydrates, 155
Rose, H. on the estimation of tellurium, 269
 M. H. analytical notes, 318
Rosolic acid and rosolates, 90
Roskilly, refining malt liquors, 178
Royal Institution of Great Britain, a course of ten lectures on inorganic chemistry, by Dr. Edward Frankland, F.R.S.—Lecture IX. 51, 65, 93
 a course of two lectures on musical acoustics, by Professor Hermann L. F. Helmholtz—Lecture II. 105
 on the relation of the vegetable and animal to the inorganic kingdom, by William Seavall Savory, Esq. F.R.S. 33
 on the physical basis of solar chemistry, by John Tyndall, Esq. F.R.S. 61
 miscellaneous notices, 14, 264, 304
Rubaseo, 124
Rubidium and Cesium, 44, 163, 219, 236
Ruhmkorff's induction apparatus, spark of, 7, 21
Ruthenium, certain properties of, 310
Rutter, R. J. on the sale of poisons, 12
Rylands, T. G. on the classification of diatomaceae, 330
SACCHARINE substance, synthetic formation of, a, 253
Saint-Edme, on the property possessed by platinum rendered incandescent by the battery to produce gaseous combination, 118
Salt-petre, C. researches on the separation by the wet way of gold or platinum from tin and antimony. Reduction of perchloride of iron by platinum, 284
Salligamine, 41
Salt-petre, 176
 production of, 153, 165, 194
 estimation of commercial, 67
Salvétat, M. preparation for gilding porcelain, 176
Sanitary condition of the City of London, 76
Savory, W. S. on the relation of the vegetable and animal to the inorganic kingdom, 23
Sawitch, M. transformation of monobromated propylene into a new hydrocarbide, 153
Scales of Lepidoptera, 331
Scafer, E. on arsenic-eating in Styria, 19
Scafigotach, M. ruthene, 124
Scheurer-Kestner, M. on the estimation of tin by standard solutions, 101, 192
Schiel, J. on the classification of organic substances by series, 191, 304
Schiff, M. compounds of ammonia with the salts of copper and cobalt, 290
Schlossberger, M. A. sensitive reagent for sulphur, 98
Schmidt, M. oil of cajuput, 124
Schnitzer, G. processes for the consecutive preparation of salt-petre, potassium-tartrate of soda, a pure bitartrate of potash, tartaric acid, and the sulphates of soda and potash, 176

- Schoonbroodt, M. transformation of cane sugar into pectic and malic acids, 291
- Schunck, Dr. on the chemical manufactures of South Lancashire, 156
- Schützenberger, M. on compounds of two acids, 333
- the fixation of ammonia, 150
- on luteoline, 150
- Science, popular, 136
- Scientific education, 291
- Scrapers, 214
- Sea-water, boracic acid in, 16
- Selenium, combinations of, analogous to sulphides, 116
- Serrott, F. W. an improved lubricating grease or paste for railway wheels and all kinds of machinery, 122
- Sesquioxide of iron, separation of phosphoric acid from, 75
- phosphate of, 158, 175
- Sewage, deodorisation of, 183, 201, 253
- Seelheim, M. on saligoline, 41
- Sharp, J. dyeing Magenta, 55
- Shopard, E. C. an improved apparatus for carburating gas for gas-lighting, 122
- Siam minerals, 28
- Signals, telegraphic night, 188
- Silica, 241
- Silicate of soda, 156
- Silicon, fluorine and mercury, salts of, 225
- in iron, 75
- Silver, assay of, by the moist way, 99, 125, 137, 204, 231, 297, 321
- chloride of, precipitation of, 201
- estimation of, in the metallic state, 75
- extraction of, from galena, 70
- nitrate of, preparation of, 98
- separation of, from mercury, 218
- substitute for, 42
- Silvered surfaces of looking-glasses or mirrors, coating and protecting, 224
- Silvering glass, 277
- Silver, H. A. on some applications of ebonite, or hard india rubber, 221
- Sloper, B. G. an improved method of, and machinery for amalgamating and for effecting the separation of gold from earthy and other matters containing the same, 69
- Smith, Dr. R. Angus, on the chemical manufactures of South Lancashire, 156
- an examination into the products of the putrefaction of blood, 293
- Smith, W. telegraphic cables, 110
- Snow and ice, relative bulks of, 268
- Soap, 316
- Soapstone of Mylos, 254
- Society, new scientific, 292
- Chemical, see Chemical Society
- Manchester Literary and Philosophical, see Manchester
- Pharmaceutical, see Pharmaceutical Society
- Royal Dublin, see Royal Dublin Society
- Soda, 156
- arseniate of, 156
- Sode carbonas siccata, preparation of, 19
- Soda, hyposulphite of, 166
- and lime, borate of, 182
- nitrate of, 98
- and potash for the attainment of antichlores, and other useful products, patent for, 11
- potassio-tartrate of, 176
- silicate of, 156
- stannate of, 156
- sulphate of, 176
- waste and sulphurets, 174
- Sodium, nitro-prusside of, 152
- and potassium, action of gases on peroxides of, 264
- selenide of, 116
- Solar chemistry, on the physical basis of, 61
- spectrum, composition of the, 293
- spot, 211
- Solder for brass instruments, 285
- Solidification of carbonic acid, 18
- Souchay, M. composition of a Roman mirror, 188
- Soundings, examination of, 263
- South Kensington Museum, on the importance of the study of chemistry, by A. W. Hofmann, LL.D., F.R.S. 7, 84
- Spanish iron ore, 164
- Sparteine, 287, 306
- Specific gravity and solid contents, 268
- Spectroscope, 178
- Spectrum analysis, 302, 328
- application of the induction coil to, 118, 130
- Dr. Miller's lecture on, 159
- Spectrum, on the blue band of the, 303
- composition of the solar, 293
- lines in solar, artificial, 140
- Spence, P. separating copper from its ores, 39
- Spieß, E. phospho-molybdate of ammonia, 75
- Spirits, copper, lead, and tin in alcoholic, 117
- Spot, solar, 211
- Squire, P. on medicinal extracts, taking extract of belladonna as an example, 275
- Stains supposed to be caused by blood, analysis of, 248
- Standard solutions, estimation of tin by, 101, 192
- Stannate of soda, 156
- Stark, M. J. colouring matters for dyeing, &c. 162
- Stas, on the relations existing between atomic weights, 124, 181, 206, 215, 228, 243, 257, 270, 282, 297, 307, 324, 335
- Steam boilers, danger of feeding with certain waters, 316
- Steel, Bessemer process of making, 112
- cast, 110, 224
- chemical composition of, 195
- electro-chemical colouring of, 5
- and iron, patent for, 110
- iron, and cast steel, patent for, 11
- Stonhouse, J. pigments for coating surfaces, 82
- Stevens, C. an impermeable protective coating for leather, 82
- a new mode of obtaining an article resembling honey, 26
- an ointment for the cure of sores, 251
- a new paste made from wood, to be used in the manufacture of various articles, 134
- Stone and cement, artificial, 185
- Stones, preservation of building, 177, 190, 200, 212, 233, 236, 247, 249, 265
- Stoppers of caustic solution bottles, 98
- Stras of diatoms, 128
- Stromeyer, estimation of oxygen in organic matters, 27
- Strontia, formate of, homihedrisism of, 310
- Strychnia, colour tests for, 2, 113
- reactions of, 75
- Substances, specific gravity of, 337
- Subterranean telegraph wires, protecting and insulating, 29
- Sugar (cane), transformation of, into malic and pectic acids, 291
- Sugar, copper test for, 286, 290
- Sugar in urine of the fox, 247
- Sullivan, W. S. on Nobert's test plate and the strise of diatoms, 128
- Sub- or oxy-sulphate of lead, 174
- Sulphate of aniline, properties of, 256
- of baryta 156
- of iron, 156
- Sulphates of copper, double, 264, 331
- of soda and potash, 170
- Sulphide of ammonium, influence of ammonia and its salts on the precipitation of certain metals by, 150
- of chromium, a new, 125
- Sulphur, in California, 320
- Influence of on fermentation, 111
- in pyrites, assay of, 276
- sensitive reagent for, 98
- Sulphurets and soda waste, 174
- Sulphuric acid, see Acid Sulphuric
- Sulphurous acid, behaviour of to iodic acid, 83
- new test for, 83
- sulphites, and bi-sulphites, and application of one of the products of such manufacture to the bleaching of textile, animal, and vegetable substances, 123
- Superphosphate of lime, 156
- Swinburne, R. W. improvements in the manufacture of plate glass, and in furnaces employed therein, 162
- Szorolmey, N. C. purifying oils and varnishes, 26
- TABLETS or show-bills, 162
- Tan, chemical products from, 288
- Tanning hides and skins, patent for, 134
- leather, 288
- Tantallic acid and thorina obtained in crystals, 102
- Tartrates of potash and soda, 176
- Tate, Mr. the boiling points of different liquids, 14
- Taylor, J. I. manufacture of gas from: coal, oil, or oleaginous substances, 316
- Tea, Paraguay, amount of theine in, 111
- Telegraphic extension, 23
- night signals, 183
- wires and cables, 26, 68, 110
- Tellurium, estimation of, 269
- Temperatures, bath for high, 319
- Test plate, Nobert's, 128
- Thouard, P. formation of fumeic acid, 136
- Theine, amount of, in Paraguay tea, 111
- Theoretical and practical chemistry, 70
- Thermometer, Casella's minimum, 235
- Thermo electric currents from one metal, 222
- Thorina and tantallic acid obtained in crystals, 102
- Thudichum, Dr. on leucic acid, 287
- Tiechborne, R. C. notes on the naphthaline colours, 197, 304
- Tin, compounds of, 156
- estimation of, by standard solutions, 101, 192
- and lead, alloys of, 316
- lead, and copper in alcoholic spirits, 117
- selenide of, 116
- separation of gold and platinum from, 284
- in vinegar, 75
- Tinctures, estimation of iodine in, 70
- Tinkalite (borate of lime and soda) from Peru, 182
- Titanic acid, detection of, 84
- Titanium, 241
- and iron, patent for alloys of, 11
- Toase, T. D. on the analysis of stains supposed to be caused by blood, 248
- Toluol, new acid from, 83
- Toothache, 201
- Townsend J. improvements in mordanting, and in the manufacture of products to be used in mordants and otherwise, 135
- Townsend, J. improvements in treating bye-products arising in the manufacture of soda and potash for the attainment of antichlores and other useful products, 11
- Trachsel, F. manufacture of gas, 289
- Tungsten, chlorides and bromides of, 163
- Tungsten, selenide of, 116
- Turnbull, Dr. on the properties of sulphate of aniline, 286
- Tyndall Dr. on the blue band of the lithium spectrum, 303
- on the physical basis of solar chemistry, 61
- UZZIEMANN, H. on some combinations of selenium analogous to sulphides, 116
- Uranium, influence of ammonia and its salts on the precipitation of, 150
- Urea from ferrocyanide of potassium, 269
- Urine of omnivora, 112
- phosphate of lime in, 287
- VANADIUM in an aluminous mineral from the South of France, 241
- from clay, 257
- Vandocasteele, L. J. brewing, 331
- Varnish, black, for zinc, 19
- for iron, 56
- Varnishes and oils, purifying, 26
- Voatch, J. A. boracic acid in the sea-water of the Pacific on the coast of California, 16
- Vegetable and animal kingdom, relation of, to the inorganic kingdom, 33
- or animal matters, preserving, 267
- substances, treatment of, and in the preparation of beverages therefrom, 161
- Ventilation, 152
- Voratric acid, 70
- Vernou, G. V. on the irregular barometric oscillations at Geneva and on the Great St. Bernard, and their relations to the mean temperature and the fall of rain, 236
- Versmann, F. bisulphide of carbon in gas, 24, 38, 82
- Vial, L. C. E. manufacture of colouring matters and pigments from coal-oil, raw naphthaline, &c., 55
- Vinegar, tin in, 75
- Vitriol chambers, economising the waste fumes from, 278
- Vulcanised india rubber, 97
- WACKER, K. oxyacanthine, 41
- Wagon, F. G. soap, 316
- Walker, J. on the estimation of nitrogen in manures and other substances, 238
- improvements in mordanting, and in the manufacture of products to be used in mordants and otherwise, 135
- improvements in treating bye-products arising in the manufacture of soda and potash for the attainment of antichlores and other useful products, 11
- Warren, G. glass, 110
- Wash for the hair, 268
- Water barometer at the Crystal Palace, 150
- Water, chalybeate, artificial, 69
- Waters from City wells, 76, 360
- feeding steam boilers with certain, 316
- Water versus Fire, 1
- gas from, 306
- hot, as an agent in warfare, 23
- its impurities and purification, 80
- on lead, action of, 172
- at Leeds, 239
- Waters, mineral, analyses of, 29
- Water, nitrates in well, 239, 253
- obtaining fresh from salt, 288
- supply of London, 76, 176, 360
- Watson, J. on certain scales of some diurnal Lepidoptera, 331
- Wax, adulteration of, with paraffin, 83
- from coca leaves, 47
- Weighting of moist precipitates, 15
- Weights, atomic, Stas on the relations existing between, 124, 181, 206, 215, 228, 243, 257, 270, 289, 297, 307, 324, 335

- | | | | |
|---|---|--|---|
| <p>White gunpowder, 13, 105, 123, 149
 lead, 43, 74
 adulteration of, 69
 and other salts of lead, 238
 zinc, and glazier's or potter's
 lead, 200
 Wilkinson, Miss D. a Guide to Croft
 Spa, 149
 Wine, estimation of alcohol in, 208
 239, 252, 258</p> | <p>Willans, J. G. the preparation of
 hydrated oxide of iron, and
 the application of such pre-
 pared oxide for the absorption
 or separation of sulphur from
 certain gases, 331
 Williams, C. H. G. dyes and colour-
 ing matters, 135
 W. M. treating coal and other
 bituminous materials, &c., 68</p> | <p>Wine, natural iodine, 302
 Wöhler, M. silicon in iron, 75
 Wood bleaching, 253
 paper from, 213
 paste from, patent for, 134
 Working in aluminium, 79
 Wormley, T. G. on Nobert's test-
 plate and the striae of diatoms, 123
 Wurtz, M. compound of aldehyde
 with oxide of ethylene, 334</p> | <p>Yeast, analysis of, 338
 Young, J. distillation of bituminous
 substances, 251
 Zinc, black varnish for, 19
 and copper alloys, 91
 influence of ammonia and its
 salts on the precipitation of,
 150
 Zinin, M. introduction of hydrogen
 into organic compounds, 164</p> |
